Precisely...

Standard for the entire metric system of lineal measurement is the International Prototype Meter, an iridio-platinum bar on which the meter is defined as the distance between two specified points. In the field of surgical sutures, DaG provides the standards by which quality and uniformity are measured. DaG sutures are the result of long experience and continuing research sciences. They can be relied on to possess the exact balance of characteristics required to assure predictable results in the specific situations in which they are to be used. As a result, sutures bearing the DaG name are preferred throughout the surgical world.

DaG Sutures

"This One Thing We Do"

DaG sutures are obtainable through responsible dealers everywhere

SCANLAN NEEDLED SUTURES... STILLE INSTRUMENTS IDEALLY SUITED FOR *Thyroidectomy*

Scanlan goiter sutures, consisting of a 30" length of sterile surgical gut, plain type A, non-boilable, size 0 or 1, with a swaged-on half-circle, full-curved, round-bodied needle, are ideally suited for goiter surgery. The single strand travels gently with least resistance and minimum traumatic effect upon the tissues.

Each step in processing Scanlan sutures is safeguarded by elaborate tests to insure uniform size, pleasing flexibility and maxi-

mum strength. Positive sterility is assured by high heat sterilizing verified by bacteriological tests.

Scanlan sutures and Stille instruments are a combination that enhances the skill and the confidence of the surgeon.

The world-famous Stille instruments, produced by master craftsmen in the A. B. Stille-Werner factory, Stockholm, Sweden, are exclusively imported by Ohio Chemical. Mail the coupon for descriptive literature.

Consider THE PADGETT-HOOD DERMATOME

*Uniform Depth of Cut In Skin
Grafts of Any Thickness*

Dermotome skin grafts are of precisely uniform thickness, cut at any predetermined level including true deep intermediate grafts. Sheets of skin up to 4 x 8 inches can be taken from any part of the body in amounts hitherto impossible, enabling the use of grafts in certain cases in which successful results have formerly been impossible to obtain.

The Dermotome consists of the precision turned drum, the cutting blade held at calibrated distances from the drum, and the supporting cradle. Its operation is simple and efficient, and greatly enlarges the scope of the field for skin grafting.

The complete set includes the Dermotome, two special steel knife blades, one honing handle for the blades, and one pint of special skin cement. (A special wood carrying and storage case for the set is also available at \$7.50)

PRICES

Dermotome.....	\$125.00
2 Special Knife Blades.....	10.00
Knife Handle for honing.....	4.50
Special Skin Cement, pint.....	1.50
Total \$141.00

Make

**YOUR INSTRUMENT
BUYING GUIDE**

The name Kny-Scheerer is more than a buy-word among the many surgeons and hospitals who predicate their choice of surgical instruments upon superior qualities that contribute to longer periods of satisfactory service. To these discriminating buyers, the K.S. trademark is a recognized symbol of correctness of design, undeviating accuracy and dependability... comparable only to quality instruments previously imported.

Significant... a cost analysis of surgical instrument expenditures often reveals the fact that purchases of instruments built up to quality are the least expensive over a given period of time.

Ohio Medical Gases Include Nitrous Oxide—Ethylene—Cyclopropane—Oxygen—Carbon Dioxide—Oxygen-Carbon Dioxide Mixtures—Helium—Helium-Oxygen Mixtures

*Ohio
Oxygen*

Naturally, you take for granted that oxygen placed in any Ohio cylinder must be pure, uniform and of highest medical quality. But the Ohio label means much more than this:

To make 100% certain that your Ohio oxygen reaches you as pure and clean as when it enters the cylinder, certain important preliminaries are necessary. First the cylinder is carefully inspected, painted, then thoroughly cleaned by vacuum to remove any slightest trace of foreign substance. Now comes the filling and the important final tests and inspections—all of these before the Ohio label is applied.

It's our insistence upon such extra precautions that insures for you oxygen of quality you can depend upon.

Ohio Nitrous Oxide

Within the cylinder a clear, colorless substance—partly liquid and partly gas. To keep Ohio Nitrous Oxide absolutely pure, cleanliness is a fetish with us. In order to assure purity of content, each empty cylinder is carefully inspected, painted, then thoroughly cleaned by vacuum to remove any trace of foreign substance. Next comes the filling and the final tests for quality and purity, last of all

Ohio Medical Gases include Nitrous Oxide—Ethylene—Cyclopropane—Oxygen—Carbon Dioxide—Oxygen-Carbon Dioxide Mixtures—Helium—Helium Oxygen Mixtures

the "Ohio" label that certifies this quality and purity to you.

It's what you can't see that makes "Ohio" the brand to specify when you order Nitrous Oxide.

Quality COUNTS, TODAY...

MORE THAN EVER, the inherently superior qualities which characterize every surgical instrument bearing the Kny-Scheerer trademark become doubly important to the discriminating surgeon during this period of national emergency.

Technical correctness of design and construction, comparable only to the finest instruments previously imported... precision accuracy, the contribution of meticulously trained craftsmen... functional dependability, the resultant use of superior materials and production methods,—all are distinctive features of basic importance. Economically, they insure longer periods of satisfactory instrument service. Clinically, they aid in the more successful attainment of the surgical objective.

TANTALUM *in Traumatic Surgery*

A SURGEON'S REPORT

"I have used tantalum wire suture material on all our hand injury cases for the past year and have a large series of them to look back upon. I have used the tantalum wire for both buried and cutane-

ous suturing. In this fairly large series of cases I have not yet seen any evidence of anything but minimal tissue reaction. I have not yet had a single infection in any of the cases where tantalum wire was used in these hand cases, which, to me, is quite remarkable because I am sure you will appreciate how difficult it is to obtain bacterial and physical cleanliness in working with the hand of the factory worker." 22

LOCAL CHEMOTHERAPY OF WOUNDS Tissue Toxicity of Certain Antibacterial Substances

EDWARD L. HOWES, M.D., F.A.C.S., New York, New York

IN this investigation the tissue toxicity of some of the newer antibacterial substances is compared with their speed of action and fate in the tissues. The substances tested were streptomycin, sulfamylon¹, calcium penicillin, parachlorophenol, tyrothricin, and zephiran.² The results of local chemotherapy with two of the antibacterial substances of low toxicity and rapid bacteriocidal action will be presented.

The antibacterial substances were tested for toxicity against cells growing in tissue culture, for the amount of irritation caused to the conjunctiva of the eye, for their capacity to damage subcutaneous blood vessels, for their capacity to destroy muscle on injection, to cause peritoneal adhesions, and to influence the rate of wound healing. Their antibacterial activity was tested in the presence of blood against the common bacteria found in the flora of wounds.

TISSUE CULTURE TESTS

The tissue culture tests demonstrated the concentration which was toxic when constantly in contact with cells. The method employed has previously been described by Simms (12).

¹The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Columbia University. Tissue culture work was done by Dr. Henry Simms, Ph.D., and Dr. Mary Parsley, Ph.D.; technical assistance furnished by Janice Kleinsorge and Joan Kennedy.
²14-amino, 2-methyl benzene sulfonamide hydrochloride = Marfanil = homosalanilamide = Mesudin.
³Triethyl ammonium chloride.

Its advantage is that the results were obtained against adult cells which possess growth requirements differing from embryonal cells.

Epithelial cells and fibroblasts from adult animals were incubated in serum ultrafiltrate for 24 hours to keep them alive and they were then transposed to chicken plasma to grow. Some were grown directly in plasma. The substances to be investigated were added in minute amounts either to the serum ultrafiltrate or the plasma as indicated in Table I. If the substance was toxic, none of the cells grew or grew very poorly. If the substance was partially toxic, the growth of the cells was poor.

Results of tissue culture tests. Bacteriocidal amounts of most of the known antiseptics killed cells. The complete data on these tests will be reported elsewhere by Simms and Parsley (11). Calcium penicillin, 100 units per cubic centimeter, was inert. Bacteriocidal concentrations of streptomycin and sulfamylon were only mildly inhibitory to cells. Streptomycin, 100 units per cubic centimeter, was inert, while 200 units were only moderately inhibitory.

Previously, streptothricin was found to be slightly more toxic; 100 units being slightly inhibitory, while 200 units were definitely toxic.

Sulfamylon, 0.15 per cent, was only moderately inhibitory while 0.1 per cent was toxic. On the other hand, zephiran (0.01%), parachlorophenol (0.001%), and tyrothricin (0.05%) were toxic to cells.

TABLE I.

Substances	Stimulating	Inert	Inhibitory	Toxic
Sulfamylon in $\frac{UF}{3}$			05%-A 46	01%-A 0
in $\frac{PI}{3}$			05%-F 44 01%-E 40	
Streptomycin		.02% (100 u) ml	.02% (200 u) ml	
Streptothricin			.02% (200 u) ml A 37	02% (200 u) ml A 1
Tyrothricin				05%
Parachlorophenol				01% E, F 0 001% A 0
Calcium penicillin in $\frac{UF}{3}$.03% (100 u) ml A 90 .003% (100 u) ml A 110 E 117		
in PI			.03% (100 u) ml	
Zephiran				.02% A 0 01% A 0
Sulfadiazine in $\frac{UF}{10}$	035% A 175 05% A 131			
in $\frac{X}{6}$.085% A 56 05% A 53 005% A 71	

UF = serum ultrafiltrate
PI = plasma
X6 = a special physiological solution
u = units

Key
A = aorta fibroblasts
E = epithelial cells
F = fibroblasts
O = no growth, over 125 stimulating, 125 to 75 = inert, 75 to 25 inhibitory, 25 to 0 = toxic

Thus zephiran, parachlorophenol, and tyrothricin, in the dilutions employed to inhibit the growth of bacteria, were toxic to cells when constantly in contact with them. Penicillin was inert while streptomycin and sulfamylon mildly inhibited the growth of cells.

EYE TESTS

The eye tests indicated the concentration of agent which would be irritating to the delicate tissues of the conjunctiva. Vasodilatation, edema, and exudate are produced if the substances are irritating. Contact with the tis-

sues is short in this test and there is considerable dilution but the tissues are very sensitive.

Two or three drops of the solution to be tested (Table II for concentrations) were placed in the eye of a rabbit and a similar amount of saline in the opposite eye. The immediate reaction of blood vessels was noted together with their condition 30 minutes later. Twenty-four hours afterward, the state of the blood vessels and the amount of edema were observed.

Results of eye tests. The results are shown in Table II. At their antibacterial concentrations nearly all the substances and sometimes even the saline caused some immediate injection of the blood vessels. Parachlorophenol (0.25%) caused more immediate redness than the other agents. At the end of one-half hour most of the treated conjunctivae had returned to their normal appearance, while those treated with calcium penicillin (200 units per c.c.), tyrothricin (0.05%) and parachlorophenol (0.25%) still showed slight redness. After 24 hours no abnormal reactions were observed with any of the antibacterial agents, indicating that except for causing a transitory reaction, none of them really injures the conjunctiva of the eye.

MUSCLE INJECTIONS

The injections in muscle indicated the capacity of the agent to cause an inflammatory reaction and fibrosis in muscle—the period of contact with the tissues was the interval between the time of injection and the absorption or neutralization of the agent.

Five to 10 cubic centimeters of the various antibacterial substances was injected in the muscles of the leg of the rabbit. To eliminate error in locating the site later, the needle was inserted anteriorly to the bone of the hind leg at a definite distance above the knee joint. In the opposite leg, the same amount of saline was injected. Twenty-four hours and 48 hours later the animals were killed and the tissues were examined grossly and microscopically. In order to be certain of the identification of the injected site in the animals living for 4 days and 1 week, a long incision was made under aseptic precaution through the skin of the back. The points of injection were marked with silk

HOWES: LOCAL CHEMOTHERAPY OF WOUNDS

3

TABLE II.—EYE TESTS—5 DROPS EACH EYE

Date	Substance	Immediate reaction	1/2 hour	Reaction after 24 hours
10-10-45	Ca penicillin 200 u. per c.c.	Slight blanching	Very slightly red	Normal
6-1-45	Streptomycin 200 u. per c.c.	Very slight reddening	Normal	Normal
6-1-45	Sulfamylon 5%	Very slight reddening	Normal	Normal
6-1-45	Streptomycin and sulfamylon mixture†	No change	Normal	Normal
10-1-45	.05% Tyrothricin	Very slight redness	Still slightly red	Normal
10-1-45	.5% p chlorophenol	Marked redness	Very slightly red	Normal
10-2-45	.5% p chlorophenol	Whole eye very red	Normal	Normal
Typical reaction in all rabbits	Saline	No reaction or very slight redness	Normal	Normal

†Consisted of 200 units of streptomycin per c.c., 5 per cent of sulfamylon, and 1/2 per cent of sodium benzoate.

ligatures in the fascia overlying the back muscle. Then the skin was resutured. The tissue immediately beneath the sutures was subsequently removed for biopsy.

Results of muscle injections. The results are shown in Table III. Zephiran produced edema, leucocytosis, and deposition of fibrin for the first 48 hours, and after 96 hours streaks of mononuclear cells could be found. Tyrothricin produced exudation and edema and finally fibrosis. Calcium penicillin produced some slight edema and exudation for the first 24 hours although thereafter no tissue reaction was observed. Streptomycin and sulfamylon produced a reaction comparable to calcium penicillin. A mixture of streptomycin and sulfamylon with sodium benzoate produced no more edema or leucocytosis than the single substances. Parachlorophenol produced a slight amount of edema and infiltration for 24 hours. After 48 hours the myosin seemed coagulated and after 1 week degenerated muscle was considerable fibrosis. Saline occasionally produced a slight exudation after 24 hours. Phenol and iodine, which were used for basis of comparison, produced frank necrosis and suppuration.

In summary, tyrothricin, zephiran, and parachlorophenol produced considerable tissue reaction and fibrosis while streptomycin and sulfamylon, calcium penicillin produced tissue reactions of such low grade that parental administration of these substances would be tolerated.

INSTILLATION IN PERITONEAL CAVITY

Only the substances which produced minimal tissue reactions were injected into the peritoneal cavity. Twenty cubic centimeters of calcium penicillin, sulfamylon, streptomycin, and the combination of the last two with sodium benzoate, were injected into the peritoneal cavity of the rabbit. Ten days later the peritoneal cavity was examined and was found to be free of adhesions.

DESIRABLE ANTIBACTERIAL PROPERTIES FOR LOCAL CHEMOTHERAPY

For local chemotherapy antibacterial substances should possess prompt bacteriocidal activity in the presence of blood. Regardless of how soluble the antibacterial substance might be, the portion of it in solution is the important component. It affects the growth of the bacteria and causes the inflammatory reactions. This portion is either quickly absorbed or neutralized while the insoluble residue is treated as a foreign body. When neutralized, this fraction loses its antibacterial properties. The portion in solution may be adsorbed temporarily on the tissue, yet thereafter rapid absorption occurs unless it has sufficient toxicity to produce an edema. Then, however, neutralization occurs.

The insoluble residue of the antibacterial substance is encapsulated by a foreign body reaction. This process of encapsulation is distorted and delayed in direct proportion to the amount of inflammatory reaction produced by the portion in solution.

SURGERY, GYNECOLOGY AND OBSTETRICS

TABLE III.—RESULTS OF INJECTION INTO MUSCLE

Substance	Microscopic appearance			
	After 24 hours	After 48 hours	After 96 hours	After 1 week
Calcium penicillin 500 u. per c.c.	Slight edema and a considerable number of leucocytes	No change.	No change	No change
Sulfamylon 5%	Occasional leucocytes. Minimal reaction. Fibrin deposits	Very slight change. Coagulation of muscle substance into irregular small pink globules. A few more leucocytes than in ordinary muscle	Slight infiltration of round cells	No change
Streptomycin	Some leucocytes. Slight edema	Nothing to distinguish it from saline. Some leucocytes	Very tiny area of new granulations between muscle fibers	No change
Streptomycin 500 u. per c.c.	No evidence of injection	No change	No tissue reaction	No change
Sulfamylon 5%	Marked edema and infiltration of leucocytes. Fibrin	Some edema and a number of leucocytes. Fibrin	Streak of mononuclear cells	
Sodium benzoate 14%	Marked edema and a considerable number of leucocytes. Fibrin	Edema and a few leucocytes. Muscle looks coagulated	Considerable destruction of muscle with replacement by fibroblasts, mononuclear and capillaries. Occasional giant cells and nest of leucocytes	Fibrosis. Giant cells. Degeneration of muscle
Zephiran 1:1000		Some leucocytes coagulated. Muscle looks coagulated	Streak of muscle coagulated	Fibrosis. Many mononuclear cells. Marked degeneration of muscle
Tyrosin 0.5%	Edema and some leucocytes. Considerable fibrin		Muscles are coagulated and necrotic. Gross destruction of muscle	
Parachlorophenol .45%			Extensive destruction of muscle with fibroblasts, granulation and round cell infiltration	
Iodine 3.5%		Slightly more infiltration of round cells. Very slight change in muscle substance		
Phenol 1%		Some infiltration of round cells	Small areas of separation of muscle fibers with heavy fibroblasts and young granulations	No change
Sulfamylon 5%	Minimal reaction			
Normal saline				

Conversely, because of the rapidity of absorption and neutralization of the portion in solution, antibacterial agents which possess only bacteriostatic activity and therefore require considerable time to act, are not useful for local chemotherapy unless the soluble portion can remain adsorbed for a long time without neutralization, or the parent substance dissolves slowly, or a base is employed slowly to release the soluble portion. The last two possibilities usually lead to continuing inflammatory reaction and fibrosis and what is more common, extrusion of the offending substance.

BACTERIOLOGICAL TESTS

To find out how a short contact with the antibacterial substances would kill bacteria, the filter paper, blood agar plate method of testing antiseptics, was adapted for our pur-

poses (2). A 24 hour culture of the particular bacteria to be investigated was streaked on a blood agar plate and the plate was incubated for 3 hours. Then a piece of filter paper dipped in a solution of the antibacterial substance was placed on the agar for 10 minutes. Ten minutes was selected because this length of time is seldom exceeded in carrying out local chemotherapy. The control area was treated with saline or not at all. The plate was then incubated for 24 hours.

Bacteria grew abundantly over the control areas and over the rest of the plate where there was no antibacterial substance, but not in the area of contact with the filter paper containing the antibacterial substance. This area remained clear. Considering that bacteria were smeared over the entire surface of the plate and that they were either growing or were

TABLE IV.—SULFAMYLON 5 PER CENT—

*Overgrowing colonies after 24 hours.

kept alive by incubating their failure to develop further in the area of contact with the agent indicated that the substance was definitely bacteriocidal. If the antibacterial substance caused hemolysis of blood this property could also be detected by the method.

About the area where the filter paper was placed there also occurred a clear zone where the bacteria did not grow. This zone varied in extent with the degree of bacteriocidal activity of the substance tested, with the sensitivity of the bacteria to the antibacterial substance and with the capacity of the antibacterial substance to diffuse through the agar.

The sensitivity of penicillin and streptomycin to acidity and dilution has been demonstrated (13, 10). Streptomycin has its optimal antibacterial activity at pH 7.8 and changes to the acid side detract from this activity. It is completely destroyed at pH 2 as is penicillin. No such information is available for sulfamylon. Hence these points were determined by the method employed.

Results. The results which are to be described are for the conditions of the experiment and should not be interpreted for different concentrations or longer contacts with the bacteria.

Sulfamylon (5%) killed staphylococci, the hemolytic and green streptococci, *Pseudomonas aeruginosa*, *Escherichia coli*, and proteus

TABLE V.—STREPTOMYCIN 200 UNITS PER
CUBIC CENTIMETER 10 MINUTE CONTACT

10-10-45	Green streptococcus	o	o

*Spread in from edges.
†Overgrown in 36 hours.

(Table IV). With all these bacteria there was a zone of inhibition about the area of contact with the paper except with the hemolytic streptococcus and pyocyaneus (*Pseudomonas aeruginosa*). Pyocyaneus was killed only within the area of contact with the paper and quickly grew in again from the edges over the cleared area.

After a similar period of contact, streptomycin, 200 units per cubic centimeter (Table V), killed the staphylococci, pyocyaneus, *Escherichia coli* and proteus. Pyocyaneus again grew back over the cleared area and more rapidly than with sulfamylon. Streptomycin was ineffective against the strains of hemolytic and the green streptococci employed. There was luxuriant growth in the area of contact with the paper.

Originally, the hypothesis was entertained that sulfamylon and streptomycin should be combined on the thesis that the former would destroy gram positive bacteria while the latter would destroy the gram negative ones. Actually when used in this manner both seem to have about the same range of bacteriocidal activity except for the streptococci. Both streptomycin and sulfamylon killed strains of staphylococci, the *Escherichia coli*, and pro-

Phenol 1%		Some infiltration of round cells	Small area of separation of muscle fibers with many fibroblasts and young granulations	No change
Sulfamylon 5%				
Normal saline	Minimal reaction			

Conversely, because of the rapidity of absorption and neutralization of the portion in solution, antibacterial agents which possess only bacteriostatic activity and therefore require considerable time to act, are not useful for local chemotherapy unless the soluble portion can remain adsorbed for a long time without neutralization, or the parent substance dissolves slowly, or a base is employed slowly to release the soluble portion. The last two possibilities usually lead to continuing inflammatory reaction and fibrosis and what is more common, extrusion of the offending substance.

BACTERIOLOGICAL TESTS

To find out how a short contact with the antibacterial substances would kill bacteria, the filter paper, blood agar plate method of testing antiseptics, was adapted for our pur-

poses (2). A 24 hour culture of the particular bacteria to be investigated was streaked on a blood agar plate and the plate was incubated for 3 hours. Then a piece of filter paper dipped in a solution of the antibacterial substance was placed on the agar for 10 minutes. Ten minutes was selected because this length of time is seldom exceeded in carrying out local chemotherapy. The control area was treated with saline or not at all. The plate was then incubated for 24 hours.

Bacteria grew abundantly over the control areas and over the rest of the plate where there was no antibacterial substance, but not in the area of contact with the filter paper containing the antibacterial substance. This area remained clear. Considering that bacteria were smeared over the entire surface of the plate and that they were either growing or were

kept alive by incubating their failure to develop further in the area of contact with the agent indicated that the substance was definitely bacteriocidal. If the antibacterial substance caused hemolysis of blood this property could also be detected by the method.

About the area where the filter paper was placed there also occurred a clear zone where the bacteria did not grow. This zone varied in extent with the degree of bacteriocidal activity of the substance tested, with the sensitivity of the bacteria to the antibacterial substance and with the capacity of the antibacterial substance to diffuse through the agar.

The sensitivity of penicillin and streptomycin to acidity and dilution has been demonstrated (13, 10). Streptomycin has its optimal antibacterial activity at pH 7.8 and changes to the acid side detract from this activity. It is completely destroyed at pH 2 as is penicillin. No such information is available for sulfamylon. Hence these points were determined by the method employed.

Results. The results which are to be described are for the conditions of the experiment and should not be interpreted for different concentrations or longer contacts with the bacteria.

Sulfamylon (5%) killed staphylococci, the hemolytic and green streptococci, *Pseudomonas aeruginosa*, *Escherichia coli*, and proteus

(Table IV). With all these bacteria there was a zone of inhibition about the area of contact with the paper except with the hemolytic streptococcus and pyocyaneus (*Pseudomonas aeruginosa*). Pyocyaneus was killed only within the area of contact with the paper and quickly grew in again from the edges over the cleared area.

After a similar period of contact, streptomycin, 200 units per cubic centimeter (Table V), killed the staphylococcus, pyocyaneus, *Escherichia coli* and proteus. Pyocyaneus again grew back over the cleared area and more rapidly than with sulfamylon. Streptomycin was ineffective against the strains of hemolytic and the green streptococci employed. There was luxuriant growth in the area of contact with the paper.

Originally, the hypothesis was entertained that sulfamylon and streptomycin should be combined on the thesis that the former would destroy gram positive bacteria while the latter would destroy the gram negative ones. Actually when used in this manner both seem to have about the same range of bacteriocidal activity except for the streptococci. Both streptomycin and sulfamylon killed strains of staphylococci, the *Escherichia coli*, and pro-

The results for the effects of changes in acidity and dilution on sulfamylon are recorded in Tables IX and X.

Comment on bacteriological test. Although the filter paper was in contact with the blood agar plate and the bacteria for 10 minutes, actually the antibacterial substance was absorbed into the agar and it was in contact with the bacteria for a much longer period of time. How long a contact is required to kill bacteria is difficult to state for the answer depends in part on the number of bacteria present and whether they are in the lag or growth phase of their development. Tests of the phenol coefficient type showed that penicillin was capable of destroying many more bacteria than either streptomycin or sulfamylon when the bacteria were sensitive to its action. Yet, a definite period of time was required for penicillin to act. For example, when penicillinase was added to a mixture of bacteria and penicillin, 4 hours' contact was found to be the period required for the penicillin to kill the bacteria. Similar substances are not available to determine the duration of contact necessary for the other antibacterial substances to act.

Clinically, no resistant bacteria should be encountered. These tests are important, therefore, only because they show that more strains of bacteria are susceptible to action of streptomycin and sulfamylon than to penicillin and that the combination of the two encounters very few resistant strains. Combinations with penicillin should be tested for their capacity to destroy various strains of bacteria.

Obviously, sulfamylon is the only drug which continues to be effective with markedly increased acidity. The change of susceptibility of *Escherichia coli* is of interest (Table X).

Influence on rate of wound healing. These tests studied the influence of the antibacterial substance on the character and length of the exudative phase of healing of the open wound and on the rate of regeneration of new tissue. The conditions which the antibacterial substance encounters on the open wound are very complex. In the open wound there is dilution of the agent by the secretions of the wound and there is constant absorption of the antibacterial substance from the surface of the wound

Fig. 1. a. Sodium sulfadiazine. b. Streptomycin. c. Sulfamylon plus streptomycin.

especially after granulations have formed. For these reasons much higher concentrations can be employed, or to state the situation conversely, granulations are not as easily damaged by antibacterial agents as are fresh tissues. Further because of the absorption, the antibacterial agents must be supplied to the wound in a base which acts as a reservoir for the material. This base must not only be innocuous but it must maintain the proper physical state of the tissues. To answer these requirements cholesterolized petrolatum was employed for the experiment though only about 2 per cent of the original content of antibacterial substance seeps from this base. On the other hand, the cells are continuously in contact with this amount of the active agent as in the tissue culture method of testing.

The open wound was made on the rabbit's ear leaving a small island of skin in the center. It was photographed every day. The character of the exudate, of the granulations, the time when the island began to grow, and the rate of its growth were observed.

The results are shown in Table XI.

These animals were killed at the end of an experiment to determine if absorption of the antibacterial substance from the wound caused damage to the excretory and neutralizing tis-

RATE OF WOUND HEALING

Results. The average index obtained was 7.5 days, i.e., for the length of time required for the exudative phase and to produce 2 millimeters of new tissue. The best rate ever obtained was 5.6 days. As can be seen from Table XI, 400 units of streptomycin combined with 5 per cent sulfamylon definitely slowed the rate of healing. Parachlorophenol gave only a fair rate and tyrosine was just average and produced a slight exudate. Granulations remained thin with it. On the other hand, excellent healing rates were obtained

with sulfamylon, 5 per cent and 1 per cent, and streptomycin, 200 units per cubic centimeter, and with the combination of these. Calcium penicillin gave only an average healing rate while sodium penicillin definitely retarded the rate of healing.

Discussion. A pattern is presented for investigating the merits of chemotherapeutic substances to use locally.

Tests will ultimately have to be conducted to determine the concentration of penicillin, sulfamylon, and streptomycin which will cause tissue reactions. Then the antibacterial activity of a slightly weaker solution will have to be studied. For example, 300 units per cubic centimeter of streptomycin or an amount

between the nontoxic 200 units per cubic centimeter and the toxic 400 units per cubic centimeter should be tried. In fairness also, it should be said that streptomycin is still in the early stages of development and products of increased purity and less tissue toxicity will undoubtedly be produced. These purified samples will have to be tested. Several reports (3, 9, 10), have been made that massive doses of penicillin produced inflammatory changes and tissue necrosis locally, but the dilution employed was not mentioned. Meddewar reported that crude penicillin (kind not mentioned) in a dilution of 1:1600 was toxic to fibroblasts after 48 hours. Herrell and Heilman found that above 500 micrograms per cubic centimeter penicillin showed cytotoxicity for lymphocytes. In other words, there is a concentration where penicillin becomes toxic. The strongest concentration of

sulfamylon which will cause tissue reaction is not even suspected. Sulfamylon hydrochloride solution 5 per cent used in these experiments had a pH of approximately 5.2 and this acidity can be neutralized without loss of antibacterial power. Theoretically, the neutralized solution should be less toxic also.

Historically, many antibacterial substances have failed as local chemotherapeutic agents because the complete pattern of requirements has not been met, *i.e.*, they were toxic or they did not act quickly in the presence of blood and pus or they were readily influenced by other changes in the environment. For example, iodine and mercuric chloride possessed none of the necessary characteristics except the capacity to destroy bacteria. More recently the sulfonamides failed because all were slow to act and were inhibited by para-amino benzoic acid. Moreover, when used as pow-

ders, as they were, the more soluble sulfanilamide was toxic while the less soluble sulfathiazole and sulfadiazine, remained as foreign bodies which were ultimately extruded from the tissues. All sulfonamides caused some reinitiation of bleeding in the wound, a property which sulfamylon possesses only to a minor degree. Some slight bleeding was observed in one instance when a very large quantity of the 5 per cent solution of sulfamylon was put into a peritoneal cavity studded with tubercles.

Penicillin has been used locally to treat staphylococcus and streptococcus skin infections and for instillations into empyema cavities. For local skin diseases penicillin is usually applied in the form of an ointment. Dry calcium penicillin powder is irritating to the surfaces of fresh wounds. Sodium penicillin is more irritating than calcium and even 200 to 500 units per cubic centimeter in saline causes a burning sensation when applied locally. No cases could be found in which clean contaminated wounds were flushed with a saline suspension of penicillin to prevent infection be-

fore suturing. There is no reason why the solution of penicillin nor it combined with streptomycin or neutralized sulfamylon should not be added to the irrigating fluid used in débridement to increase the antibacterial range of that fluid. Dry penicillin powder has been placed in wounds to be sutured and in open wounds. Those which are to be left open, especially those with granulation, tolerate dry penicillin well but dry powders of any of antibacterial substances, even when they exhibit low toxicity, should not be used in wounds which are to be sutured. A saturated solution results which may be toxic as the work with penicillin suggests (5, 3, 10), and besides saturated solutions are not needed for antibacterial action.

Although penicillin has been repeatedly injected in lesser concentrations into muscle for parenteral administration, injections of a solution of it about an area for the prevention or treatment of an infection has not been practiced. In the frankly infected wound, penicillin is not effective because of the excessive

amounts of dead tissue present, and penicillin is destroyed in the presence of gram negative bacteria. The prediction can be made also that streptomycin and sulfamylon will not be successful in the local treatment of the purulent wound even though both substances have wider range of antibacterial activity than does penicillin. Local chemotherapy will not be successful in the presence of slough until there is also a chemotherapy of slough. Yet, the published reports on the local use of sulfamylon are optimistic.

Nearly all bacteriologists who have worked with sulfamylon have proposed that the drug should be used for local treatment of wounds, but only Mitchell, Reese, and Robinson have published their results. They applied powdered sulfamylon to 22 purulent wounds including 4 burns. In one-third of the cases, no growth could be obtained on cultures after 4 to 12 days' treatment, and 70 per cent showed improvement. The German Army apparently made extensive use of sulfamylon for the local treatment of wounds, but their records are not available.

In experimental animals, Hamre, Walker, Durham, Van Dyke, and Rake showed that sulfamylon is one of the most effective agents for the local treatment of gas gangrene although they used comparatively small amounts of the drug. They recommended a clinical trial of local treatment and also noted that its acute and chronic toxicity was of low order. The *in vitro* activity of sulfamylon against the anaerobic gas forming micro-organisms has been confirmed by others (9, 14). There is universal agreement in the literature that sulfamylon is not inhibited by para-amino benzoic acid (1, 8) and that unlike penicillin it is not destroyed by penicillinase.

These experiments also demonstrated that changes in the acidity of the wound would not destroy the activity of sulfamylon except against *Escherichia coli*. Locally, a concentration of 3 per cent or greater must be maintained.

The local use of streptomycin is reported for the first time in this publication. It was used in combination with sulfamylon. Sutured wounds and certain types of open wounds were successfully treated. On the other hand,

TABLE XI.—INDEX OF WOUND HEALING*

Animal No.	Amount in cholesterolized petrolatum	Index	Remarks
569	1% sulfamylon	6.8	Excellent healing

*Index = days required for exudative phase plus days required to produce 2 millimeters of new epithelium. Average Index = 7.5. Best rate ever obtained = 5.6 days.

local applications of the combination, like penicillin, were not too successful in ridding the open wound of infection. Why the combination was successful in certain types of wounds and not in others had best be explained.

Local chemotherapy of the open wound is a more complex problem than chemotherapy of the sutured wound. Some of the difficulties encountered in treatment of the open wound have been pointed out already. Besides the open wound is recontaminated with bacteria at every dressing, the bacterial flora changes and the bacteria develop fastness for the chemotherapeutic agent. Then slough must be liquefied for slough is a nutrient and protector of the bacteria. On the other hand, in the sutured wound the bacterial contamination is complete at the time of suturing. The tissues are freshly injured and easily injured again by the agent. The chemotherapeutic agent can be used once only at the time of closure of the wound.

Among open wounds and inflammatory conditions which were free of slough, 68 wounds, burns, and rectal conditions were treated with the solution of sulfamylon and streptomycin. Satisfactory results were obtained without

THE GASTRIC DIGESTION OF LIVING TISSUE

PHILIP B. PRICE, M.D., and TUNNIE F. LEE, M.D., Salt Lake City, Utah

ALTHOUGH the digestion of dead animal tissue ingested as food is well understood, the digestion of living tissue, especially autogenous tissue, remains obscure. Why the stomach does not digest itself during life is a question that has never been answered satisfactorily. John Hunter postulated a "vital principle" in all living tissues which prevents digestion, but the presence or nature of such a "principle" has not been demonstrated. Obviously different tissues vary in their ability to withstand the corrosive action of gastric juice. Secretions which are quite innocuous in the healthy stomach may simply irritate the walls of a gastric fistula but cause painful erosions of the skin at the mouth of the fistula. The question of autodigestion has long interested physicians, partly as a matter of scientific curiosity, but chiefly because it is related intimately to such clinical problems as the pathogenesis and healing of peptic ulcer, the violent peritonitis which follows acute perforation, perforations which invade the pancreas or liver, anastomotic jejunal ulcer, gastrotrophic fistula, and the destructive effects in the lungs of aspirated gastric contents.

Claude Bernard in 1859 showed that the leg of a live frog thrust through a fistula into a dog's stomach is soon digested away. The same is true of a rabbit's ear (8). Observers have not been in agreement, however, regarding the digestion of experimental autoplasmic grafts. Katzenstein, Kathe, Best, and others claimed that living spleen, intestine and omentum implanted in a dog's stomach are digested, but opposite results were obtained by Holtz, Licini, and Tietze (6). Mann and others (2, 6, 7) have shown that patch transplants of jejunum, so placed that only the mucosa of the intestine is exposed to gastric contents, remain unchanged for long

periods of time (as long as 1½ years) unless they are situated at the lesser curvature, in which case ulcers often develop in the grafts.

A more detailed study of autodigestion was made by Dragstedt and his associates (3, 4). These investigators reported that the intact spleen, kidney, and pancreas implanted in openings in the anterior wall of the stomach or duodenum of dogs are not digested even after several weeks, and they concluded that these living organs resist the digestive action of normal gastric and duodenal contents. Patch transplants of small intestine were found to be digested, however, by the pure secretions of an isolated stomach or a Pavlov pouch. So also was the spleen. It was observed, furthermore, that intestinal loops implanted with the serosal surface exposed to gastric juice undergo partial digestion with the formation of smooth round perforations. Dragstedt and his coworkers decided that the outer layers of the intestinal wall are less resistant than the mucosa to the digestive action of gastric juice.

The present investigation has extended those observations. Our early experiments showed that small windows in the normal canine stomach heal so rapidly that the digestive effects of gastric juice are masked by the processes of repair; consequently, in most of our experiments large openings were made through which tissues or organs were deeply implanted in the lumen of the stomach, thus insuring prolonged full exposure to gastric contents. Special pains were taken to preserve normal or adequate blood supply in the tissues tested.

About 135 dogs were used in these experiments. Stock laboratory animals were employed, operations being done aseptically under pentobarbital sodium anesthesia. Fine cotton thread was used for ligatures and sutures. Water and food (dog pellets) were permitted freely after operation. The animals were explored surgically or were sacrificed after various intervals. Autopsies were per-

From the Department of Surgery, University of Utah Medical School, Salt Lake City.

Aided by grants from the Doctors' Research Fund and the Rockefeller Third Research Fund of the University of Utah School of Medicine.

Fig. 1. Three methods used to expose living omentum to the action of gastric juice: A, a small oval window in the stomach covered with a tab of omentum; B, a large

window covered with a thin patch of omentum; C, a large tongue of omentum inserted through a window into the lumen of the stomach.

abdominal wall. In both animals the omentum still embedded in the abdominal wall appeared perfectly normal on gross and microscopic examination.

Finally, small pieces of omentum were grafted on the serosal surface of the anterior gastric wall so as to receive their blood supply entirely from it. Some of these free grafts had the appearance of normal fatty omental tissue, while others were (by design) more or less fibrosed; but all were living and healthy. The transplants were subsequently turned into the lumen of the stomach on pedicle flaps of gastric wall (Fig. 6). In this way living omentum, having undergone various degrees of fibrosis, was exposed to gastric juice. In most instances these omental grafts were digested in from 6 to 18 days, although a small island of fat surrounded by fibrous tissue was found in one instance after 44 days. It was not determined whether the fibrous grafts were digested more or less rapidly than the more normal fatty tissue.

It may be concluded, therefore, that healthy living omentum is digested when deeply implanted in the stomach, but placed patch-like over a gastric window it becomes fibrosed and suffers only superficial digestion.

2. *Digestion of living intestine.* The digestion of part of an isolated segment of jejunum which protruded into the stomach has already been noted. In that experiment it was obvious that all the layers of the intestinal wall had undergone digestion, although the destructive process ceased abruptly at the level of the gastric wall (Fig. 4 B).

An isolated piece of jejunum with intact mesenteric blood supply was sewed patchlike in a gastric window so that only its mucosa was exposed to gastric juice (Fig. 7). This experiment has been done many times by earlier investigators and our results are similar to theirs. No changes were detected in this flat jejunal implant after as long as 262 days.

It was found, furthermore, that after a graft of this sort had "taken" its mesentery could be divided without injury to the patch. When, however, the jejunal transplant was invaginated into the gastric lumen (a) by infolding that part of the stomach with sutures, or (b) by turning in a pedicle flap of gastric wall including the transplant (as in Fig. 6), digestion of the jejunal mucosa occurred, although adjacent comparable gastric mucosa remained normal.

Intact loops of jejunum and ileum were also implanted in the stomach so as to expose the serous surface to gastric juice. When small windows were used, relatively little digestive action was observed and the gastric defects healed rapidly. When the loops were deeply implanted in large windows, however, (Fig. 8) perforation and digestion of the exposed intestinal wall regularly occurred. Areas of necrosis and perforation were observed as early as 2 days after implantation; after 11 days extensive necrosis and multiple perforations were found; after 27 days digestion of the exposed wall was nearly complete with formation of smooth gastrointestinal mucosal junction. Figures 9 and 10 show clearly one stage in that digestive process.

Fig. 3. Photomicrograph of an omental implant after 21 days, showing the edge of the residual crater illustrated in Figure 2. Proliferating gastric epithelium is seen in the upper right-hand corner, as well as a small quantity of necrotic debris about to be sloughed into the lumen of the stomach. The base of the ulcer shows superficial necrosis, cellular infiltration, granulation tissue, and fibrosis; the underlying omentum is fibrotic.

later after having passed bloody stools. The implanted kidney of this animal showed extensive necrosis and digestion, and the stomach and intestines were full of blood. The second dog was very ill when sacrificed 4 days after operation. A similar picture was presented of necrosis and digestion of the implant with hemorrhage into the stomach. The remaining 3 dogs, sacrificed on the 14th, 16th, and 29th days, respectively, showed partial digestion of the implant, extensive fibrosis of the exposed parenchyma, and areas of hemorrhage, infection, and necrosis (Fig. 17).

After many failures we succeeded in one dog in implanting part of the inferior lobe of the left lung in the stomach which had first been herniated through the diaphragm. The omentum, drawn up with the stomach, was tucked around the implant to prevent leakage. This animal, which remained healthy, was sacrificed on the 15th day. There had been no slipping of the structures or leakage of gastric contents. The implanted lung was found to have been digested entirely away, leaving a healing gastric stoma around a circular necrotic crater. Two other dogs, dying 2 days after operation from leakage of gastric contents and infection, showed only atelectasis

Fig. 4. Omentum implanted after it has been threaded through a cuff of jejunum. One edge of the jejunal cuff was pushed into the gastric window and fastened there so as to protect the omentum from strangulation. A, the original implant; B, a sagittal view of the result after digestion had occurred.

and hyperemia of the implant and inflammation of its pleura.

4. *Digestion of living connective tissue.* In 8 dogs large round holes were made in the anterior gastric wall and the margins of the holes were sutured to the parietal peritoneum so as to expose the abdominal wall itself to the digestive action of gastric juice. After 24 hours there was hyperemia of the exposed parietal peritoneum; after 9 days the peritoneum had disappeared and there was fibrosis and digestion of the abdominal wall; after 36 days fibrosis and digestion were more marked with the production of an ulcer a few millimeters deep, the margins of which showed

Fig. 5. A tongue of omentum implanted after passage through a tunnel in the abdominal wall. The margins of the gastric window were sewed to the parietal peritoneum so that the omentum could not be constricted by the stomach.

Fig. 6. Steps in the preparation and implantation of free living grafts of omentum: A, omentum fastened to the gastric wall covering a scarified area; B, parent omentum cut away after the graft had taken; C, 1 or 2 weeks later, a pedicle flap of gastric wall cut so as to include the graft; D, invagination of the flap and its parasitic graft and closure of the defect; E, sagittal view of the implant.

healing and active proliferation of gastric epithelium. One dog after 64 days had a large deep ulcer involving the fascial and muscular layers of the abdominal wall.

By a multiple-stage operation a long pedicle flap of skin was raised from the anterior abdominal wall and the free end of the flap was placed in the peritoneal cavity. A week later this flap, which appeared quite healthy, was implanted in the stomach by making a large hole in the anterior gastric wall and sewing the margins of the hole to the abdominal wall around the flap, as was done with the omentum in Figure 5. In this way we insured good circulation of skin while exposing it directly and continuously to gastric juice. One such dog sacrificed 11 days after implantation showed partial digestion of the flap, especially its subcutaneous tissue. In another dog more advanced necrosis and digestion were seen

after 18 days, although the hair on the graft had grown appreciably during the period of implantation. Histologic examination of these specimens shows that epidermis is more resistant than the dermis or subcutaneous tissue to the digestive action of the gastric juice. In a third dog sacrificed after 21 days the flap had digested away entirely.

We also planted free whole thickness skin grafts, 1 to 2 centimeters in diameter, on the anterior serosal surface of the stomach and on the parietal peritoneum near the stomach. The skin took readily on these surfaces. The grafts on the stomach were implanted by turning in pedicle flaps of gastric wall (as in Fig. 6), and the grafts on the parietal peritoneum were exposed by suturing the margins of a gastric window to the abdominal wall around them (as in Fig. 5). Partial digestion of these skin grafts was noted as soon as the

Fig. 7. An isolated segment of jejunum with mesentery attached, opened along its antimesenteric border and sewed patchlike in a large gastric window. The patch is trimmed to fit the window neatly so that only jejunal mucosa is exposed to the gastric contents.

12th day after implantation, but islands of residual epithelium could be found histologically even after 2 months.

The ends of the 10th and 11th ribs were freed and brought into the peritoneal cavity; a few days later about 3 centimeters of one or both ribs was implanted in the stomach. Complete digestion of these cartilaginous structures to the level of the gastric stoma occurred in from 12 to 17 days.

5. *Digestion of living gastric tissue.* Small and large areas of gastric mucosa were excised so as to expose the underlying submucous and

muscular coats of the stomach to the digestive action of its own secretions. The smaller denuded areas healed rapidly. One area 1.5 by 2.5 centimeters in size was completely healed in 12 days, leaving only a minute puckered scar. On microscopic examination the muscle underlying this scar appeared perfectly normal. Larger denuded areas, 3 to 5 centimeters in diameter, required 4 to 6 weeks for healing. None of these artificial "ulcers" perforated, but histologic examination showed pronounced fibrous reaction involving the muscle layers. When, however, large portions of the stomach

Lumen of Stomach

Fig. 9. Sagittal view of a deep jejunal implant after 27 days. Most of the implanted intestine had digested away leaving a large gastrojejunal fistula. The seromuscular surface of the jejunum was much more seriously affected by gastric juice than was the mucous membrane. Microscopic examination of the margins of the fistula showed no proliferative activity on the part of the jejunal mucosa, but on the other hand there was no evidence that the intestinal mucosa had been digested until its underlying wall was destroyed and its blood supply cut off. The area within the square is shown in greater detail in Figure 10.

Fig. 10. Jejunal wall 27 days after implantation. Normal mucosal glands and submucosa are seen on the right, but the seromuscular layer has almost entirely disappeared. A thick layer of typical granulation tissue is seen on the left. This surface was exposed directly to the gastric contents.

(e.g., the entire antrum and prepylorus) were deprived of mucous membrane, healing was delayed in some instances for several months. Multiple small deep ulcers were occasionally seen in these unhealed defects, and one dog died on the 49th postoperative day from perforation and peritonitis.

Fig. 11. Section showing violent reaction of the serous surface of the colon after several days' exposure to gastric juice. The seromuscular coat is acutely inflamed with extensive necrosis. The margins of a perforation, not seen in this view, gives no evidence of proliferative activity of intestinal epithelium.

In 2 animals short wide flaps of gastric wall, 2.5 by 5 centimeters in size, were raised,

Fig. 12. Result of a deep liver implant after 26 days. The portion of the lobe, several centimeters in length, which protruded into the stomach, had digested away, leaving a shallow crater with a necrotic base. The surrounding gastric epithelium shows moderate proliferative activity.

Fig. 13. Photomicrograph of the necrotic base of the crater illustrated in Figure 12. Beneath the layer of necrosis seen in the upper right-hand corner, is a zone of fibrosis, granulation tissue, and cellular infiltration. Liver cells appear at the bottom of the picture. A small developing abscess may be observed in the lower right hand corner of the picture.

Fig. 14. Photomicrograph of a pancreatic implant after 24 days. Frank necrosis may be seen in the upper part of the field; below, islands of pancreatic cells in various stages of deterioration are separated by fibrous and granulation tissue.

stripped of mucosa, and were then sutured back in place. In this way we attempted to expose to digestion a portion of gastric wall which lacked a protective covering of mucosa, had been subjected to a certain amount of operative trauma, and had had its circulation somewhat disturbed. These defects healed at about the same rate, however, as the denuded areas described in the preceding paragraph. There was pronounced fibrosis of the exposed muscle, but no real ulceration or perforation.

Finally, in a series of 11 dogs we turned pedicle flaps of gastric wall into the lumen of the stomach (Fig. 18). The flaps were so cut that they received an abundant blood supply from the vessels of the lesser curvature, shown by free bleeding from the tips and sides. Two of these flaps had the mucosa removed and consequently were composed of only the outer layers of the gastric wall. They were completely digested in 2 to 3 weeks. The flaps which contained mucosa showed early digestion of the serosa and muscle and delayed digestion of the mucosa; in fact, the mucous membrane had a tendency to enfold and pro-

tect its supportive structures (Fig. 18). In 2 animals in which the mucosa completely enveloped the other coats, the flap after 3 to 4 weeks had the appearance of a cone of mucosa projecting into the gastric lumen. These poly-poid structures remained unchanged as long as the dogs were observed (33 and 91 days). When this protective envelopment by the mucosa failed to occur or was incomplete, the pedicle flaps disappeared in 2 to 4 weeks, leaving ulcers in the stomach wall at the site of the base of the flaps. In these animals it is

Fig. 15. Photomicrograph of an implanted spleen after 19 days. Digestion had occurred to the level of the gastric stoma. A thin zone of acute inflammatory reaction, hyalinization, and necrosis overlies the splenic parenchyma which retains its structural characteristics.

probable that the seromuscular layers of the flaps were destroyed and that the mucosa, deprived of support and circulation, thereupon underwent digestion also.

OBSERVATIONS

It may be questioned whether additional factors such as strangulation, infarction, infection or autolysis may not have contributed to the results which we have called gastric digestion. The question of constriction actually arises only in the case of solid tissues or organs where more or less unyielding structures are implanted through a gastric window which in time undergoes contraction. In those preparations care was taken to avoid constriction at the time of implantation, and subsequent microscopic examination of the implanted tissues shows the vessels in most instances to be normally filled with blood. Moreover, abnormal cellular changes are found as a rule only at or near the corroding surface and not in the body of the implant as would be expected if the circulation of the entire implant were compromised. Since our implants were all made in the normal fasting acid stomach, a high percentage of infections would

Fig. 17. Photomicrograph which shows the digesting surface of a deeply implanted kidney. Superficially necrosis and acute inflammatory reaction are noted; more deeply can be seen hemorrhage, fibrosis, cellular infiltration, and granulation tissue, as well as a degenerating glomerulus and the remains of collecting tubules.

not be expected and in fact were not found. Leucocytic infiltration and abscesses were observed in some of the implants, but that was exceptional. Histologic examination also appears to rule out autolysis as a primary factor in the so called digestion since there was no generalized deterioration of cells throughout the implant. The evidence seems fairly conclusive, therefore, that living tissue of all sorts may actually be digested in the stomach, either directly or after necrosis has occurred, in the absence of contributing factors such as strangulation, infection and autolysis.

Living tissues vary in susceptibility to gastric digestion. Judged by the time required for digestion when placed in the stomach tissues may be arranged tentatively in order of resistance of digestion. Most susceptible are the seromuscular coats of the intestine and gall bladder; next, omentum and cartilage; then kidney, spleen, lung, liver, and pancreas; and most resistant of all, fibrous connective tissue, skin, and intestinal mucosa.

The only tissue which appears to be completely immune to ordinary gastric digestion

is the epithelium of the stomach. Thin sheets of regenerating gastric epithelium, even those which seem to be poorly supported and nourished by underlying structures, show no signs of injury from gastric juice. The reason for this immunity is not clear. It has been suggested that the presence of a protective coat of mucin prevents digestion, but Dragstedt and his associates state that the most advanced cells in the proliferative process may be entirely devoid of mucin. It is noteworthy that tissues, once covered by regenerating gastric epithelium, are protected from digestion. This is an important feature of the process of repair in the stomach.

An impression gained from this study is that fibrosis, a reaction most strikingly seen in the omentum, hinders digestion and therefore acts as a protective mechanism for more highly differentiated tissue. Granulation tissue seems to provide an even more resistant surface. It is important to note in this connection that certain tissues respond to the presence of acid pepsin with considerable fibrous reaction and round cell infiltration, whereas others undergo disintegration and digestion at the surface without much reaction.

Tissues also vary in the type of reaction to gastric juice. Serous surfaces in general become acutely inflamed with leucocytic infiltration and necrosis, as in Figure 11. The omentum and the capsules of liver, spleen and kidney usually respond with excessive amounts of fibrosis, as in Figures 3 and 16. The parenchyma of solid viscera characteristically present complex pictures of fibrosis, hemorrhages, cellular infiltration, and necrosis (Figs. 13, 14, 15, and 17). Some tissues, muscle for example, tend to produce granulation tissue at the corroding surface, as in Figure 10. Epidermal surfaces seem to erode slowly with little or no cellular reaction.

Organs and tissues which project into the lumen of the stomach are much more rapidly and completely digested than are those placed tangentially in a gastric window. An attractive conjecture is that deep implants, lacking adequate protective coats of mucin, are subject to digestion, whereas tangential implants and residual craters of digested implants are protected from the full corrosive effects of

Fig. 18. Method of turning a pedicle flap so as to expose the structures of the gastric wall to the digestive action of its own secretions. The small figures illustrate the tendency of such flaps to curl, the more resistant mucosa enveloping the less resistant seromuscular layer.

acid pepsin by mucin from the surrounding gastric mucosa.

It should be noted finally that a number of our animals appeared toxic, some were quite ill in fact, during the period of necrosis and digestion of the implants; but these animals recovered full health after the necrotic tissue had disappeared. This phenomenon was observed particularly after implantation of intestines, gall bladder, and solid organs.

SUMMARY AND CONCLUSIONS

An experimental study has been made to determine whether or not living tissues are susceptible to ordinary gastric digestion. Many different tissues, including omentum, intestine, liver, gall bladder, pancreas, spleen, kidney, lung, cartilage, skin, and even the gastric wall itself, were subjected to gastric digestion in healthy dogs. The test was made by means of implanting living tissues and organs in the lumen of the stomach or by insuring prolonged surface contact with gastric secretion.

This phenomenon was observed particularly after implantation of intestines, gall bladder, and solid organs.

SUMMARY AND CONCLUSIONS

An experimental study has been made to determine whether or not living tissues are susceptible to ordinary gastric digestion. Many different tissues, including omentum, intestine, liver, gall bladder, pancreas, spleen, kidney, lung, cartilage, skin, and even the gastric wall itself, were subjected to gastric digestion in healthy dogs. The test was made by means of implanting living tissues and organs in the lumen of the stomach or by insuring prolonged surface contact with gastric secretion.

Virtually all the tissues and organs so tested underwent digestion. There is evidence that this digestion occurred, in many instances at least, in the absence of contributing factors of strangulation of the implant, infarction, infection, or autolysis.

The tissues most rapidly digested were the external coats of hollow organs (intestines, appendix, gall bladder); those most resistant were fibrous connective tissue, skin, and intestinal mucosa. The seromuscular coat of the stomach itself was not exempt from auto-digestion. The one tissue which seemed to be immune to ordinary digestion was gastric epithelium.

Organs and tissues projecting into the lumen of the stomach were much more rapidly and completely digested than were those which were placed tangentially in a gastric window.

Living tissues undergoing digestion showed different sorts and degrees of reaction. Serous surfaces in general became acutely inflamed with rapid leucocytic infiltration and necrosis. The omentum and the capsules of liver, spleen, and kidney responded with excessive amounts of fibrosis. The parenchyma of solid viscera characteristically presented complex pictures of fibrosis, hemorrhages, cellular infiltration, and necrosis. Some tissues, muscle for example, tended to produce granulation tissue at the corroding surface. Epidermal surfaces slowly eroded with little or no cellular reaction.

Histologic study suggests that a surface of active fibrosis offers a certain amount of resistance to digestion, that even more opposition is offered by a layer of granulation tissue, and that these surfaces act as barriers to the destructive action of acid chyme. Such tissue responses are probably of practical importance since they serve as protective mechanisms, delaying the progress of corrosion until healing can take place by means of fibrous contraction of the gastric defect and proliferation of gastric epithelium across the base of the ulcer. Once tissues are covered with proliferating gastric epithelium, they appear to be safe from further corrosive action of normal gastric juice.

A number of the dogs appeared toxic during the period of necrosis and digestion of the implants, but recovered full health after the necrotic tissue had disappeared.

THE LOCAL APPLICATION OF NITROFURAN COMPOUNDS WITH SPECIAL REFERENCE TO USE ON WOUNDS

M. C. DODD, Ph.D., F. W. HARTMANN, Sc.D., and W. C. WARD, M.S.

IN a previous report (4) a series of nitrofurán compounds was shown to be bacteriostatic and bactericidal for a variety of gram positive and gram negative organisms in low concentrations. Further work has established the fact that the bactericidal activity of several of these compounds is not abolished by the presence of blood or serum.

Previous work has also shown that some of these compounds are nontoxic for laboratory animals in moderately large doses.

These facts suggested the possible clinical use of nitrofurán compounds in the treatment of infected wounds. In order to test the value of this suggestion as far as possible in the laboratory and to provide maximum information to the clinician, an examination was made of the irritant properties, toxicity, and effect on the healing rate of wounds in rabbits produced by the local application of nitrofurán compounds. For this purpose, five of these compounds previously shown to have excellent antibacterial properties *in vitro* were selected. The 5 compounds chosen were—

	$R = O_2N - \text{furan ring}$	Solubility in water
5-nitro-2-furyl methyl ketone	$-R-COCH_3$	1-250
5-nitro-2-furaldehyde semicarbazone	$-R-CH=N-NHCONH_2$	1-5000
n-propyl-5-nitro-2-furoate	$-R-COOC_3H_7$	1-10,000
5-nitro-2-furfuryl propionate	$-R-CH_2OOC_2H_5$	1-1000
ethyl β -(5-nitro-2-furyl) acrylate	$-R-CH=CHCOOC_2H_5$	1-15,000

The first four may be regarded as derivatives, in the order named, of furan, 2-furaldehyde, 2-furoic acid and 2-furfuryl alcohol, while the last named compound is related to β -(2-furyl) acrylic acid.

The relatively low solubility of four of these compounds in water has already been indicated. For the following experiments they were incorporated into a water soluble base composed of polyethylene glycols (carbowaxes) and propylene glycol.¹ The semicarbazone and the furoate

formed pharmaceutically acceptable preparations in this base while the other three compounds caused a progressive discoloration of the base. However, *in vitro* tests on the discolored products showed no loss of antibacterial activity even after storage for 1 year.

In these experiments this base was found to be quite suitable as a vehicle for the application of these antibacterial compounds. All of the nitrofurán compounds are soluble in the base thus providing a vehicle by which greater concentrations of the compounds could be applied than would be otherwise possible unless the compounds were placed directly on the wounds. In avoiding this latter procedure, a more economical preparation was obtained even though the concentrations used in the base are many times the minimum bactericidal concentrations of the compounds. Keeping in mind that the primary clinical use for these compounds would be in the treatment of infected wounds, a preparation of this kind also avoids the caking and interference with wound drainage so frequently encountered with powdered preparations and heavy ointments. In addition, the slight surface active properties of carbowaxes, plus the fluidity of the preparation at body temperature should provide a mechanism for a maximum of spreading and mixing of the compounds with body fluids even when pus or other organic material is present. Finally, the preparation being washable can be removed readily with water and facilitates observation and redressing of wounds.

The base alone was used as a control in the experiments on the healing rate of treated wounds. It is nonfatty, contains no water, and possesses physical characteristics suitable for use as a vehicle for local application. Extensive work by Smyth and coworkers (13, 14) has demonstrated the lack of toxicity and irritation of the carbowaxes for laboratory animals and that they produced no more irritation in human subjects than such commonly used bases as petrolatum and glycerin. Friedman has shown that carbowax 1500 is also nontoxic for rabbits when given intravenously in large doses. Numerous investigations (1, 6, 7, 10, 16) have been reported on the safety of propylene glycol for human use.

¹Carbowax 1500—55%
Carbowax 4000—20%
Propylene glycol—25%

IRRITATION TESTS ON HUMAN SKIN

The five aforementioned nitrofurantoin compounds were tested for possible irritation effect on human skin. Four compounds, the ketone, semicarbazone, furoate and furylacrylate were used at a concentration of 1:500 in the base, while the propionate was tested at a concentration 1:100 in the same preparation. All five preparations were applied to the forearms of each of 10 volunteers for 2 successive days. Following application, the areas used were covered by small dressings. Sufficient material was applied to insure its presence on the skin for 24 hours. Observations of all areas were made at 6, 24, and 48 hours following application.

Table I shows that none of the five nitrofurantoin compounds was irritating after 6 hours contact. After 24 hours one subject showed hyperemia of the skin due to the presence of the furylacrylate. After 48 hours, 6 individuals out of 9 gave evidence of irritation due to this same compound,

while 3 out of 9 persons were affected by the ketone. None of the reactions were more severe than a moderate hyperemia. Apparently, these two compounds possess irritating properties for two-thirds and one-third, respectively, of the individuals tested at the concentrations used in the experiment. The other three compounds gave no evidence of irritation in any of the subjects in the concentrations tested.

EFFECT OF FIVE NITROFURAN COMPOUNDS ON THE HEALING RATE OF EXPERIMENTAL WOUNDS IN RABBITS

For this experiment the 5 nitrofurantoin compounds here mentioned were incorporated into the washable base in three different concentrations. The ketone, furylacrylate, semicarbazone and furoate were made up in concentrations of 1:500, 1:1000, and 1:5000 in the base, while the propionate was compounded at 1:100, 1:500, and 1:1000. These concentrations were selected rather arbitrarily, al-

TABLE II.—HEALING TIME IN DAYS OF WOUNDS TREATED WITH 5-NITRO 2-FURYL METHYL KETONE

Concentration	Average healing time for wounds on ventral surface	Average healing time for wounds on dorsal surface	Average healing time for all wounds	Shortest healing time for any wound	Longest healing time for any wound
1:500	21	22	19	12	28
1:1000	20	16	18	11	26
1:5000	17	17	17	10	22
Base	15	17	16	10	20
Untreated	14	14	14	10	16

though all of them are many times the minimum bactericidal concentration for these compounds as determined by *in vitro* methods. The fact that the previous experiment had shown the 1:500 concentrations of the ketone and furylacrylate to be irritating suggested that these concentrations would also interfere with the healing process, thus providing some information on the maximum concentration permissible for wound treatment. The following data, however, do not support this expectation since these concentrations show very little effect on the healing process, though they may not be optimal for use on healing wounds.

Twenty rabbits were used in the experiment and 5 to 8 wounds were inflicted on each rabbit. After removal of the hair from either the dorsal or ventral surface of the rabbits, the wounds were made with a rongeur and scalpel. The technique employed produced wounds quite similar in size and of equal depth. The wounds averaged 175 square millimeters in area and extended down to the muscle. The wounds on the ventral surface were observed to stretch more and become larger than those on the dorsal surface, which was attributed to the thinness and lack of connective tissue in the former as compared to the skin on the back.

The three concentrations of each compound in the base were applied to these wounds, and the effect on the healing rate was compared with untreated wounds and wounds treated with the base alone. The test substances were reapplied every 2 days, and sufficient material was applied to cover the wounds completely. The wounds were protected by small gauze and adhesive bandages ("Band Aid") and removal was prevented by cloth jackets tied around the rabbits. Their progress in healing was followed by the method of Carrel and Hartmann. Before each treatment tracings of the wounds were made on cellophane. These were transferred to plain white paper for measurement with a compensating polar planimeter. The process of healing was thus measured and recorded until complete healing occurred, which for these experiments was defined as the time when the new epithelium over the wound became continuous.

Fourteen days after the wounds were made biopsies obtained from those treated with each of the concentrations of the five compounds as well as from the control wounds were subjected to histological examination for evidence of possible irritation or injury due to nitrofurans compounds and as a further comparison of healing rates.

The results of this experiment can best be considered by presentation of the data obtained on

Fig. 1. Healing rates of wounds treated with 5-nitro-2-furyl methyl ketone, 1:500, 1:1000, and 1:5000 in a washable base. The inhibitory action of the three concentrations of the compound on epithelization is apparent after the 16th day.

each compound in order. A total of 130 wounds were observed, each compound being used on 18 wounds, 6 on each of the 3 concentrations employed. The tables and graphs which follow are based on the data obtained from 3 to 6 rabbits. Two control wounds were used on each animal, one untreated and one to which the base alone was applied.

The effect of 5-nitro-2-furyl methyl ketone on the healing rate of wounds in rabbits is demonstrated in Table II and Figure 1. A comparison of columns 2 and 3 in Table II shows that the variation in healing time between wounds on the dorsal and ventral surfaces of the animals was not significant. Column 4 demonstrates that the average healing rate was inhibited by this compound, the degree of inhibition increasing with the concentration. Columns 5 and 6 show that the process of wound repair progressed at a very different rate from animal to animal, emphasizing both the individual differences between animals and the value of controls on each.

Since the decrease in the area of the wounds between successive measurements varied directly with the rate of healing, the average areas of the

Fig. 3. Rabbit 2 on the 10th day of treatment with 5-nitro-2-furyl methyl ketone (N.P. No. 135). Wounds. Upper left, 1:500. Upper right, 1:1000. Middle left, 1:5000. Middle right, base alone. Lower left, untreated.

wounds were plotted against time for a graphic presentation of the effect of the various concentrations of the ketone on the healing rate. Experience had shown any significant variation in the process of wound repair to occur in the second half of the total healing period, hence the initial wound areas presented in all the graphs included here are those obtained on the sixth day of treatment.

Figure 1 shows the marked similarity in the rate of healing of all wounds used in the study of 5-nitro-2-furyl methyl ketone, but also demonstrates the inhibitory effect produced by this compound on the rate at which final epithelization of the treated wounds occurred. The initial sizes of the wounds were similar, and the healing rate curves all have essentially the same slope until about the sixteenth day. From this point on, during the time when the process of epithelization was observed to be the major repair process, the

inhibition of healing produced by the compound is apparent. It should be recalled that this compound was irritant to intact human skin at a concentration of 1:500.

The gross appearance of the wounds treated with 5-nitro-2-furyl methyl ketone and with the base alone was essentially the same as the untreated wounds (Figs. 2, 3) except that the latter did not develop as heavy a crust as the treated wounds.

Table III presents the observations made on the healing time of wounds treated with ethyl 8-(5-nitro-2-furyl) acrylate. In this group of animals the wounds on the dorsal surface healed more rapidly than did those on the ventral surface. Columns 5 and 6 again emphasize the individual differences in animals, showing that the slowest healing wounds required more than twice as much time as the fastest. The data in column 4 indicate that the test compound had no appreciable effect on healing when present at a concentration of 1:5000, but did produce a slight extension of healing time at 1:1000 and 1:500.

Figure 4 graphically demonstrates the inhibitory effect of the higher concentrations of ethyl 8-(5-nitro-2-furyl) acrylate on the healing of wounds as compared to controls treated with the base alone and to untreated controls. This effect appears to be similar to that produced by the previously described compound in that it occurs late in the process of healing, at the time of final epithelization, although the effect in this instance is not as marked. Grossly all wounds appeared similar (Figs. 5 and 6).

The data in column 4, Table IV, show that the third test compound, 5-nitro-2-furfuryl propionate definitely slowed the healing process in all three concentrations employed, although this effect was no more marked at 1:100 than it was at a 1:1000 concentration. Columns 2 and 3 again show that wounds on the back healed a little sooner, and columns 5 and 6 emphasize the previous data pointing to the wide variability in the healing rate of wounds on individual animals.

TABLE III.—HEALING TIME IN DAYS OF WOUNDS TREATED WITH ETHYL 8-(5-NITRO-2-FURYL) ACRYLATE

Concentration	Average healing time for wounds on ventral surface	Average healing time for wounds on dorsal surface	Average healing time for all wounds	Shortest healing time for any wound	Longest healing time for any wound
1:500	19	16	17.3	12	26
1:1000	20	13	16.5	10	28
1:5000	16	14	15	10	24
Base	16	14	15	10	22
Untreated	15	13	14	10	22

Fig. 4. Healing rates of wounds treated with ethyl β -(5-nitro-2-furyl) acrylate, 1:500, 1:1000, and 1:5000 in a washable base. The higher concentrations prolong the healing time of wounds as compared to the control wounds. This effect is most apparent in the period after the sixteenth day.

Figure 7 illustrates the slight prolongation of healing time produced by all three concentrations of this compound as compared to the control wounds. The gross appearance of the treated wounds as shown in Figures 8 and 9 was not significantly different from those receiving no treatment.

The results of the treatment of wounds with *n*-propyl-5-nitro-2-furoate are presented in Table V. The figures in column 4 indicate that this compound had no significant effect on the healing

process as noted with the previous compounds. The apparently anomalous result of 17.5 days average for the healing of wounds treated with a concentration of 1:1000 must be discounted as perhaps due to some unrecognized error, since wounds treated with both the larger and smaller concentrations healed, on the average, in a period of time equal to that of the untreated controls and somewhat sooner than that of those treated with the base alone. The previously noted tendency of wounds on the back to heal more quickly than on the ventral surface is again apparent in this group of animals as listed in columns 2 and 3. Again, the variability in the healing of wounds on individual animals is emphasized by the shortest and longest healing time observed for any wound given in columns 5 and 6.

Figure 10 illustrates the similarity of all wounds in this group both treated and untreated, empha-

TABLE IV.—HEALING TIME IN DAYS OF WOUNDS TREATED WITH 5-NITRO-2-FURFURYL PROPIONATE

Concentration	Average healing time for wounds on ventral surface	Average healing time for wounds on dorsal surface	Average healing time for all wounds	Shortest healing time for any wound	Longest healing time for any wound
1:200	18	16	17	12	24
1:500	17	16	16.5	10	24
1:1000	18	16	17	11	24
Base	15	13	14	10	20
Untreated	14	12	13	11	16

Fig. 7. Healing rates of wounds treated with 5-nitro-2-furfuryl propionate, 1:100, 1:500 and 1:1000 in a washable base. All three concentrations slowed the rate of treated wounds as compared to wounds treated with the base alone or untreated wounds.

sizing the lack of any inhibitory action due to the presence of this compound (see also Figs. 11 and 12). Even the previously noted and unexplained results obtained with wounds treated with a concentration of 1:1000, do not produce a markedly dissimilar healing rate or modify the gross appearance of all the wounds in this group.

The results in Table VI are from wounds treated with 5-nitro-2-furfuraldehyde semicarbazone. Column 4 shows that this compound is like the previous one in that none of the three concentrations tested had any inhibitory effect on the rate of healing as compared to either wounds

Fig. 8, left. Rabbit No. 5 on the 10th day of treatment with 5-nitro-2-furfuryl propionate (N.P. No. 225), 1:100, 1:500 and 1:1000 in a washable base. Wounds. Upper left, 1:100. Upper right, 1:500. Middle left, 1:1000. Middle right, base alone. Lower left, untreated.

Fig. 9. Rabbit No. 6 on the 10th day of treatment with 5-nitro-2-furfuryl propionate (N.P. No. 225), 1:100, 1:500, and 1:1000 in a washable base. Wounds. Upper left, 1:100. Upper right, 1:500. Middle left, 1:1000. Middle right, base alone. Lower left, untreated.

treated with the base alone or untreated wounds. In fact, wounds treated with a concentration of 1:1000 of this compound showed an average healing time shorter than the controls. Figure 13 emphasizes the similarity of the healing process of all wounds in this group of animals, and Figures 14 and 15 show the wounds on two of these rabbits on the tenth day of treatment.

In summary, it can be noted that three of the nitrofurans compounds tested, 5-nitro-2-furyl methyl ketone, ethyl β -(5-nitro-2-furyl) acrylate and 5-nitro-2-furfuryl propionate caused a slight prolongation of the healing time of wounds in rabbits, while no such effect was observed in wounds treated with either n-propyl-5-nitro-2-furoate or 5-nitro-2-furfuraldehyde semicarbazone. No other effect was noted with any of the compounds. A review of the tabulated general average healing periods for wounds treated with the

Fig. 12. Rabbit No. 8 on the 10th day of treatment with n-propyl-5-nitro-2-furoate, (N.P. No. 245), 1:500, 1:1000, and 1:5000 in a washable base. Wounds. Upper left, 1:500. Upper right, 1:1000. Middle left, 1:5000. Middle right, base alone. Lower left, untreated.

2.5 per cent, neutral acriflavine 2.5 per cent, and gentian violet in water) extended healing time of burns in rabbits, 5 and 40 days respectively.

A histological examination of tissue taken from both treated and untreated wounds on animals in all test groups on the fourteenth day of treatment was done. The results corroborated the above observations that the only effect produced by the compounds was a slight inhibition of healing by the three named above. This examination failed to emphasize even this effect since little or no difference could be found between treated and untreated tissue regardless of the compound used.

TOXICITY OF NITROFURAN COMPOUNDS BY ABSORPTION FROM LARGE WOUNDS

The following experiment was designed to determine possible toxicity of the nitrofurans.

TABLE VI.—HEALING TIME IN DAYS OF WOUNDS TREATED WITH 5-NITRO-2-FURALDEHYDE SEMICARBAZONE

Concentration	Average healing time for wounds on ventral surface	Average healing time for wounds on dorsal surface	Average healing time for all wounds	Shortest healing time for any wound	Longest healing time for any wound
1:500	16	13	14	10	20
1:1000	10	13	11.5	10	14
1:5000	14	12	13	10	16
Base	14	13	13.5	10	16
Untreated	15	11	13	11	16

Fig. 13. Healing rates of wounds treated with 5-nitro-2-furaldehyde semicarbazone, 1 500, 1 1000, and 1 5000 in a washable base. No inhibitory effect on the healing rate was observed in wounds on which this compound was employed. The wounds treated with a 1 1000 concentration healed even faster than the controls.

pounds discussed in the work described by continuous absorption from large wounds when the compounds were present over a prolonged period. The conditions are thus similar to the clinical use of local antiseptics on large wounds. Toxicity under such conditions depends on, first, absorption of the compound, and second, its toxic properties.

An idea of this second factor for each of the five compounds tested can be gained from the data to be given on the L.D. 50 for mice and rats by the oral and subcutaneous routes of administration. It must be borne in mind, however, that these figures cannot be applied directly to rabbits on which the present work was done, but merely

Compound	L.D. 50—Mice orally mgm./kgm.	L.D. 50—Rats subcutaneously mgm./kgm.
5-nitro-2-furyl methyl ketone	400	200
5-nitro-2-furaldehyde semicarbazone	600-700	>3000
n-propyl-5-nitro-2-furoate	1200	>2000
5-nitro-2-furfuryl propionate	300	700
ethyl β -(5-nitro-2-furyl) acrylate	3500	>4000

Fig. 14. left. Rabbit No. 9 on the 10th day of treatment with 5-nitro-2-furaldehyde semicarbazone, (N.P. No 2-20-90), 1 500, 1 1000, and 1 5000 in a washable base. Upper left, 1 500. Upper right, 1 1000. Middle left, 1 5000. Middle right, base alone. Lower left, untreated.

Fig. 15. Rabbit No. 10 on the 10th day of treatment with 5-nitro-2-furaldehyde semicarbazone, (N.P. No 2-20-90), 1 500, 1 1000, and 1 5000 in a washable base. Upper left, 1 500. Upper right, 1 1000. Middle left, 1 5000. Middle right, base alone. Lower left, untreated.

serve to indicate the toxicity found under controlled methods of administration.

Because of the lack of a chemical test to determine the presence of the compounds in the blood, the dosage applied to the wounds in this experiment was large, with the hope that toxic symptoms might be produced which could be detected by either gross or microscopic methods, thus indicating the occurrence or lack of absorption. Accordingly, the animals were exposed to approximately 250 milligrams per kilogram of each compound continuously for a month as indicated. This dosage is obviously much lower in many cases than that given, but the fact of the continuous presence of the compounds made the conditions rather severe.

The method of application consisted of the preparation of large wounds with areas of approximately 25 to 50 square centimeters on the ventral surface of the rabbits to which the compounds were continuously applied for a period of 4 weeks. The appropriate dose of the substance was concentrated in approximately 2 grams of the washable base previously described and applied to a square piece of gauze which was placed over the wounds and held in place with adhesive tape. A cloth jacket was then tied in place over all to protect the dressings. The compounds were applied immediately after the wounds were made and at weekly intervals afterward. This ensured an excess of material in contact with the wounds

at all times. Weight records, blood examinations and blood urea nitrogen determinations were done before and after the treatment period. Urine analyses were useless because of the tendency of many apparently normal rabbits to albuminuria. At the termination of the experiment, all animals were sacrificed and the tissues were studied microscopically.

5-Nitro-2-furyl methyl ketone was the only one of the five compounds tested to produce death or symptoms of toxemia. The 2 rabbits treated with this compound as outlined died in 24 to 48 hours. Four more rabbits treated by the same method but with a dosage of 100 to 200 milligrams per kilogram also died in 1 to 2 days. However, 50 and 65 milligrams per kilogram were applied, as has been described, for a full month without any symptoms of toxemia, nor did the histological examination reveal any abnormalities present in any of the tissues.

The other four compounds were used at the stated dose on two rabbits each for the full experimental period of 4 weeks without any symptoms of toxemia appearing. None of the rabbits showed a significant weight variation. The blood picture was essentially normal, the only possible significant finding being a slightly lower hemoglobin value. Blood urea nitrogen determinations were well within the limits determined on normal rabbits. The histological examination of the tissues of these animals was also entirely negative for any abnormalities attributable to the compounds.

Observations were made on the wounds during this period although because of the large concentration of compounds present no attempt was made to measure the effect on healing. However, no gross sign of irritation was observed. Heavy crusts or scabs formed over all wounds regardless of the compound applied. However, differences were observed. Ethyl β -(5-nitro-2-furyl) acrylate, *n*-propyl-5-nitro furoate and 5-nitro-2-furaldehydes emicarbazone caused a considerable quantity of tough, elastic necrotic tissue to be formed in wounds on which these compounds were present. Less of this material was noted in wounds treated with 5-nitro-2-furyl methyl ketone and none was found when 5-nitro-2-furfuryl propionate was used.

As a result of this experiment it can be concluded that four of the five compounds discussed here are nontoxic for rabbits when applied to large open wounds in doses of approximately 250 milligrams per kilogram of body weight continuously for 4 weeks. One compound, 5-nitro-2-furyl methyl ketone, is toxic under similar conditions,

causing the death of rabbits in 1 to 2 days. However, no toxicity was encountered when the quantity of chemical applied was reduced to 50 to 65 milligrams per kilogram.

COMMENT

Previous work has established the antibacterial action of the five nitrofurans compounds discussed here, which suggested an investigation of their possible use in the local treatment of infected wounds. Compounds intended for such a purpose should also be nonirritating to human skin, nontoxic on local application to large denuded areas for long periods of time; produce no adverse effect on healing, and the antibacterial activity should not be abolished by organic matter.

The present work has demonstrated that two of the five compounds studied, *n*-propyl-5-nitro-2-furoate and 5-nitro-2-furaldehyde semicarbazone qualify as efficient antibacterial substances which are nonirritating and nontoxic under conditions of local application and do not delay the healing process in wounds in rabbits. In addition, Neter has shown that 5-nitro-2-furaldehyde semicarbazone was effective in the treatment of wounds in rabbits infected with hemolytic streptococci.

As a result of these studies, 5-nitro-2-furaldehyde semicarbazone (designated as furacin) was deemed worthy of clinical trial. It was incorporated 1:500 in the washable base which was previously described for use on infected wounds in humans.

At the time of this writing, Snyder, Kiehn and Christophersen have prepared a preliminary report on a small series of cases of infected wounds treated with this preparation in which favorable clinical and bacteriological results were obtained and have recommended its further trial. They have also noted the lack of toxicity, irritation, and interference with healing which has been described in the present work on rabbits. Several other clinical trials are being conducted by McCollough and by Shipley who corroborate the earlier findings of Snyder and his associates.

Certain justifiable criticisms have been made recently of the experimental method used in this work as a valuable measurement of the healing rate of wounds. It has been pointed out by several workers that the method records chiefly the rate of contraction of the wounds and that it is not an accurate measurement of the rate of epithelization.

No attempt is made here to refute these criticisms, since the aim of this investigation was to provide as much information as possible with the

methods available on the properties of these compounds under conditions of continuous local application.

It is interesting to note, therefore, that the findings recorded here by the method of Carrel and Hartmann on the failure of 5-nitro-2-furaldehyde semicarbazone to interfere with healing were substantiated by the histological findings. It has also been shown by those investigating the clinical utility of this compound that epithelial grafts covered with it have consistently given excellent results and that no interference with the rate of epithelialization was indicated.

SUMMARY

Five nitrofurane compounds of previously proved antibacterial activity were tested for irritation to human skin and for toxicity and effect on healing when applied to wounds in rabbits. Two compounds, *n*-propyl-5-nitro-2-furoate and 5-nitro-2-furaldehyde semicarbazone were found to be nonirritating, nontoxic, and have no adverse effect on healing under the conditions of the experiments. Because of its superior antibacterial activity, 5-nitro-2-furaldehyde semicarbazone has been recommended for clinical trial in infected wounds and preliminary trials show favorable clinical and bacteriological results.

MALIGNANT LESIONS OF THE DUODENUM

CLAUDE F. DIXON, M.D., F.A.C.S., A. L. LICHTMAN, M.D., HARRY M. WEBER, M.D.,
and JOHN R. McDONALD, M.D., Rochester, Minnesota

KNOWLEDGE gained in the performance of pancreatotomy and in the post-operative care of the patients is applicable to the surgery of malignant lesions of the duodenum and papilla of Vater. The circumvention of the difficulties involved in the partial removal of the pancreas and duodenum with provision for the re-establishment of biliary and alimentary continuity is the same for all three lesions.

PATHOGENESIS

The rarity of carcinoma of the small intestine has provoked extensive discussion (13). Like the fallopian tubes and the spleen, the small intestine is so infrequently the site of a primary malignant lesion that it prompts search for some factor causing refractoriness to malignant change. If some of the hypotheses of the causation of cancer are correct, duodenal malignant lesions should be common. Let us take trauma as an example. The horizontal or third portion of the duodenum lies over the third lumbar vertebra and therefore is exposed to trauma. The duodenojejunal flexure, where fixed intestine becomes free, is a frequent site of duodenal rupture. Looking for sites where chronic irritation is common, one finds that the duodenum is a retort that is constantly charged with acids, alkalis, enzymes, bile salts, cholesterol, and the things we eat and drink. Chronic duodenal ulcers and erosion around duodenal fistulas are evidence of irritative properties of the duodenal contents.

Advocates of the hypothesis of malignant degeneration in gastric ulcers must assume some inhibitory influence in the duodenum. In 3 of the cases studied in this paper the pathologist seemed to concur with Jefferson's opinion (15), drawn from 30 collected cases, that carcinoma of the duodenum may result from malignant degeneration in an ulcer (4). But it may be pointed out that carcinoma of the duodenum does not show the predilection for the first inch of the duodenum that characterizes duodenal ulcer, even though, like duodenal ulcer, it is more common among men than among women. Critical examination of Jefferson's case reveals that the lesion may have

been a carcinoma from the very first. He assumed that, because the lesion was diagnosed as a benign ulcer by palpation and 2½ years elapsed before the carcinoma was obvious, the lesion was originally benign. Examination of our cases shows that the patient may live for many years after gastroenterostomy for duodenal carcinoma. Even if every carcinoma in the first part of the duodenum resulted from a duodenal ulcer, the incidence of duodenal carcinoma is so small as compared with that of duodenal ulcer that only an infinitesimal percentage of duodenal ulcers would undergo malignant degeneration.

Duodenal mucosa makes contact with gastric mucosa, two pancreatic ducts and one biliary duct. The cells of Brunner's glands perforate the muscularis mucosae. Robertson has reviewed the difficulties that confound the diagnosis of carcinoma of the duodenum. He observed that Brunner's glands are extremely passive and do not undergo any special or prominent alterations under abnormal conditions. Brunner's glands are most abundant in the first few inches of the duodenum and in the tissue surrounding the papilla of Vater. Review of the literature on the few cases in which malignant changes have occurred in the cells of Brunner's glands reveals that paradoxically the only carcinomas arising unquestionably from the cells of Brunner's glands are questionable carcinomas. Robertson presented data on one case in which there was unorganized hyperplasia with cells showing hyperchromatism, irregular arrangement and occasional mitotic figures. Since then we have encountered a surgical case in which proliferative changes in the cells of Brunner's glands were great enough to suggest to some of the pathologists examining the lesion that it was a definite carcinoma (Fig. 1). This case is not included in this series because its status is open to question.

Then there is the possibility of malignant degeneration in heterotopic tissues (9). In 23.5 per cent of cases of aberrant pancreatic islands, the aberrant tissue occurred in the duodenum (6). Diverticula may contain ectopic pancreatic or gastric mucosa (8,27). In this respect it is interesting to note that in 3 of the cases in this series diverticula were present and in 1 case an aberrant pancreatic nodule was found. Polyps, adenomas,

From the Division of Surgery and the Sections of Roentgenology and Surgical Pathology, Mayo Clinic.

Fig. 1. Very low grade carcinoma of the duodenum in which the cells seem to have originated from the cells of Brunner's glands.

and papillomas may also undergo malignant change. It is surprising that carcinoma of the duodenum is not more common than it is. From our study we concluded that carcinoma of the duodenum may originate from any of the cells mentioned, but the bulk of the lesions represent anaplastic changes in the duodenal mucosa itself. If any of the processes mentioned contributed a considerable number of the lesions, this would be reflected by an increased incidence at the site of predilection of that process. In our series after exclusion of cases of carcinoma of the papilla of Vater the lesions were quite evenly distributed throughout the duodenum. Those who dismiss as imaginary the possibility of malignant change ever occurring in certain benign lesions of the duodenum must assume some extraordinary resistance conferred on the tissue by their presence (2).

The duodenum is rarely the site of metastatic lesions from other organs. Of course, as it progresses, carcinoma from the pancreas, because of its proximity, may perforate through the duodenum. No tissue will stop in very case the invasive growth of contiguous carcinoma. It is said that carcinoma of the stomach will stop short at the pylorus and carcinoma of the cecum will stop at the ileocecal valve but exceptions are encountered from time to time. Furthermore, such a lesion may stop abruptly at its contact with the small intestine and yet invade a loop of ileum or jejunum from without a short distance away.

Lieber, Stewart and Lund (17), Stewart and Lieber (26), and Berger and Koppelman have presented excellent reviews of reported cases of carcinoma of the duodenum. Bringing their figures up to date and including the cases presented here that have not been reported pre-

viously, one may state that 718 cases have been reported, of which 433 are acceptable. Considering that many cases are unreported, it is apparent that the lesion is not as rare as textbooks state it to be. Roughly, it occurs about 33 times in 100,000 necropsies (based on Eger's 350,286 collected necropsies) as compared with 3,000 times for carcinoma of the stomach. It comprises 0.3 per cent of intestinal carcinomas (12).

Because the cases in the literature are derived predominantly from postmortem material, we have avoided an elaborate analysis of the symptoms, which are usually terminal, representing the invasion of contiguous structures. This fact was demonstrated in several of the cases studied here, in which histories of the same patient taken a year or more apart by independent observers revealed how readily a patient forgets early symptoms when more distressing symptoms overshadow them.

MATERIAL FOR STUDY

There are 45 cases of surgical and 4 of non-surgical malignant lesions of the duodenum in the records of the Mayo Clinic (15 of these cases have already been reported—11,16,20,24). In 13 cases the lesion was verified at necropsy. This study does not include carcinoma of the ampulla or papilla of Vater, which entails the possibility of lesions arising from the common bile duct, the ducts of Wirsung and Santorini, the ampulla or the papilla. Cases in which the pancreas was involved were omitted from this study unless the study of the edge of a slowly growing lesion revealed that it was of duodenal origin. Probably some cases of duodenal carcinoma are classified as pancreatic or vaterian, since at the time of examination the lesion has extended so far in some cases that its primary location cannot be ascertained. However, such cases must be credited to the more common lesion; that is, pancreatic or vaterian carcinoma. A brief analysis of the proved cases is presented here to elucidate some of the points of interest to the surgeon.

PATHOLOGY

In 44 of the cases the lesion was carcinoma of the duodenum. In 2 it was sarcoma, in 2 leiomyosarcoma and in 1 lymphangioendothelioma, which showed involvement of the regional lymph nodes. In 2 of the cases there were simultaneous independent gastric carcinomas and in 1 there was a synchronous lesion of the jejunum. In 3 cases a duodenal ulcer was coexistent and in 1 there was aberrant pancreatic tissue. Polypoid lesions were twice as frequent as ulcerated lesions. There have

Fig 2. Sharply demarcated constricting deformity in the descending (second) portion of the duodenum, with obliteration of the folds of mucous membrane in the deformed part. These features identify the lesion as a neoplastic one.

been many attempts in the literature to attribute significance to the cylindric type of carcinoma or the spheroidal form, to hard scirrhous or soft medullary forms, but we found such distinctions of little value. As in carcinoma at other sites, the grade (Broders' method) of the lesion, the involvement of the lymph nodes and local or distant extension determined the prognosis.

INCIDENCE

Age. In the majority of the cases the patients were in the sixth or seventh decade. The average

Fig 3. Crescentic deformity in the horizontal (third) portion of the duodenum. The tumor was mostly intramural. The roentgenologic diagnosis was "leiomyoma."

age of the patients who had carcinoma was 55.4 years. The youngest patient who had carcinoma was 26 years of age, 1 was 39 years, 8 patients were in the fifth decade, 18 in the sixth, and 16 in the seventh. The age of both patients who had leiomyosarcoma was 38 years. The sarcomas occurred at 17 and 64 years and the lymphangioendothelioma occurred at 27 years of age.

Fig 4. Lesions of neighboring organs causing deformity in the duodenum. a, Carcinoma of the head of the pancreas extending into and causing ulceration in the duodenum and displacing it downward and toward the right side. b, Carcinoma of the hepatic flexure of the colon extending

to and involving the duodenum. c, Lymphoblastoma of the retroperitoneal lymph nodes constricting a long portion of the duodenum without actually invading it. In all instances the extrinsic nature of the lesions was suspected at roentgenologic examination.

Fig. 5. a and b, Deformity of the first portion of the duodenum caused by primary carcinoma; the roentgenologic diagnosis was "duodenal ulcer." c and d, Deformity in the second (descending) portion of the duodenum caused by benign peptic ulcer, the roentgenologic diagnosis was "ulcerating lesion" but neoplasm was suspected.

Sex. Thirty of the patients who had carcinoma were men and 14 were women. The patients who had leiomyosarcoma were both men while the 2 patients who had sarcoma were women. The patient who had lymphangioendothelioma was a man.

Distribution. Fourteen of the lesions occurred in the first part of the duodenum, 15 in the second, and 20 in the third part. In collected series the greatest number is found in the second part. This is the result of the inclusion of vaterian carcinomas by many authors.

DIAGNOSIS

Because of their rarity, as compared with duodenal ulcers complicated by obstruction or bleeding, malignant lesions of the duodenum may frequently go undiagnosed. Experience at the clinic since 1938 has demonstrated that if both the clinician and the roentgenologist are on the lookout for such lesions, roentgenologic examination

will be extended to include the entire duodenum and thus make a morphologic diagnosis possible. Many of the reviewers, following the lead of Pic, have devoted much effort to the differentiation by symptoms of lesions of the suprapapillary, peripapillary, and infrapapillary regions of the duodenum. They have gone into great detail, taking cases in which the lesion was discovered at necropsy, then going back and studying the record. We might say that one is doing well if one suspects the presence of a lesion of the pancreas, bile duct, or duodenum strongly enough to suggest that roentgenologic examination of the upper part of the gastrointestinal tract include the second and third portions of the duodenum. That is the way that definitive diagnoses were made in this series.

The symptoms of duodenal carcinoma are frequently present over a relatively long period. The average duration before admission was 11.8 months, with 2 patients giving a history of 6

Fig. 6. Two examples in which carcinoma of the duodenum caused obstruction of relatively high degree. In a,

left, the roentgenologic diagnosis was "obstructing lesion"; in b, the roentgenologic diagnosis was "carcinoma."

years' duration. In the cases studied here the symptoms appeared to be a result of the morphologic characteristics of the lesion rather than of its position. Four processes within the lesion seemed to account for the symptoms regardless of whether it was in the first, second, or third part.

Obstruction by a napkin ring stenosis or by an intraluminal polypoid lesion was most common. The latter type seemed to produce more cramps and borborygmi than the former. With long-standing obstruction there is dilatation of the stomach and duodenum and observing patients may note the splash of the gastric contents produced by gastric retention. The vomitus will contain bile in lesions of the third part but be clear in lesions of the first part. However, pressure on the bile ducts by lymph nodes may alter this.

Second, the lesion may ulcerate or slough, producing bleeding. The first indication of the disease to some patients is weakness and fatigue produced by anemia. Some of the patients seen in the early history of the clinic had been treated by their physicians for pernicious anemia for many months, but blood smears soon showed that the anemia was a result of chronic loss of blood. It has frequently been suggested that there is some defect in the absorption of the intrinsic factor (23) in cases of duodenal carcinoma, but loss of blood was demonstrated in all cases in this series in which there was anemia. No cases in which there was macrocytic hypochromic anemia were encountered in this series. This is understandable when one observes that a relatively small portion

of the duodenum is involved by carcinoma. Meulengracht has suggested that the specific antianemic intrinsic factor is elaborated by the parts of the "pyloric gland organ," which is represented in the duodenum by Brunner's glands. In interpreting his hypothesis one should remember that hemopoiesis is not changed much after total duodenectomy and partial gastrectomy. The very low incidence of pernicious anemia after total gastrectomy is being studied now. Probably the critical test will come when total gastroduodenectomy is performed.

The third process that modifies the symptoms is perforation into the pancreas, in which case the pain of a pancreatic malignant lesion or pancreatitis may occur.

The fourth process that we wish to mention is obstruction of the biliary or pancreatic ducts. Carcinoma of the duodenum encroaching on the papilla of Vater will produce symptoms similar to those of vaterian or pancreatic carcinoma. One cannot assume from this that the lesion is in the second part of the duodenum, for involved nodes derived from a lesion of any part may cause jaundice, the first symptom, by pressure on the ducts. Occasionally there are points that aid in the differentiation. If the jaundice is preceded by signs of obstruction, one may suspect extension of a duodenal carcinoma. Intermittent jaundice favors the diagnosis of a duodenal lesion but a vaterian lesion may change its degree of obstruction by sloughing or reduction of inflammatory edema. Extrinsic involvement of a small segment of the common duct may produce obstructive

Fig. 7 Duodenum and part of jejunum and pancreas with the carcinoma of the duodenum.

Fig. 8. Photomicrograph of carcinoma of the duodenum (X125).

jaundice even though a probe can be passed through the lumen easily at operation. In this series there was no case in which there was enough hepatic involvement to produce jaundice. In fact, the few metastatic regions in the liver that were seen were small.

Pain in the epigastrium or right upper quadrant of the abdomen was the most common chief complaint. It was present in 38 cases. It frequently began 1 to 4 hours after meals and was relieved by vomiting or sodium bicarbonate but not by food or milk. The onset was sudden in 6 cases and pain came on at night in 7 cases. The pain was usually steady but in 10 cases it was cramplike. The absence of extension of the pain was so uniform that when extension did occur one could assume perforation into the pancreas or obstruction of one of the ducts. Twenty-seven of the patients complained of bloating and belching. Gastric retention was advanced enough to produce frequent vomiting in 16 cases. In many of these cases the patients discovered that they could avoid retention by taking a liquid diet. In 4 cases retention vomiting had produced frank tetany with the concentration of chlorides in the region of 300 milligrams per 100 cubic centimeters of plasma, that of urea at 125 milligrams per 100 cubic centimeters of blood, and carbon dioxide combining power more than 70 volumes per 100 cubic centimeters of plasma (19).

In 6 cases the only complaint was of progressive weakness and fatigue. These cases presented a diagnostic problem until examinations of blood and stool revealed a bleeding gastrointestinal lesion. The concentration of hemoglobin was less than 6 grams per 100 cubic centimeters of blood in 17 of the cases and more than

13 grams per 100 cubic centimeters of blood in 12 of the cases. Hematemesis was present in 9 cases and melena in 12 cases. No portion of the duodenum showed a greater predilection for bleeding or obstructive lesions than any other.

Jaundice was present in 8 cases. It was a late manifestation in all except the 1 case reported later. In half of the 8 cases of jaundice, the lesion existed in the second part of the duodenum. In 3 cases it was in the first part and in 1 it was in the third part. Thus one cannot conclude that the lesion is periampullar in cases of jaundice. In the 222 cases of periampullar carcinoma of the duodenum collected by Lieber, Stewart, and Lund (18), jaundice was present in all but 4 cases. In 41 per cent (26) of cases of carcinoma of the supra-ampullar region jaundice was present. This greater incidence of jaundice in the collected series than in our series results from the fact that in almost all of the cases the patient was in the terminal stages of his condition when he was observed. In a large proportion of the cases in this series in which palliative operation was performed, jaundice developed shortly before the patient's death.

Alteration of frequency of evacuation or of consistency of the stools is not a common symptom in cases of carcinoma of the duodenum. The presence of typical diarrhea would make one suspect obstruction of the pancreatic duct. This is found in 35 per cent of cases of vaterian carcinoma (5).

Loss of appetite is not a common symptom among patients who have carcinoma of the duodenum. If one excludes the flatulence often present with gastric retention, only 2 of the patients complained of loss of appetite. One sees a

Fig. 9. Diagrams showing the situation of the lesion. The shaded area in the diagram on the left shows the extent of the region removed. The diagram on the right reveals the connections established between the biliary ducts and stomach and the jejunum.

similar situation among patients who have prolonged gastric retention after gastroenterostomy. They often complain of great hunger even when as much as 1,000 cubic centimeters of gastric contents is retained. In 16 of the 29 cases in which analysis of gastric contents was performed, anacidity was noted. The free acid content was high in 1 case, normal in 6, and low in 6. The average loss of weight in this series was 22 pounds (10.0 kgm.). The gall bladder was palpable in 2 cases. In 10 cases a mass was palpated in the upper part of the abdomen. In cases of carcinoma of the duodenum, the abdomen is usually flat and without gaseous distention.

ROENTGENOLOGIC DIAGNOSIS

Most reviewers state that a roentgenologic diagnosis of duodenal neoplasm is rarely made. Until relatively recent times this may have been true. However, that the roentgenologic diagnostic maneuvers, which have been used so successfully in the diagnosis of lesions in the esophagus, the stomach, the first portion of the duodenum and the large intestine, can be applied with almost equal success to the diagnosis of lesions of the small intestine is a fact that is becoming ever more widely appreciated. Weber and Kirklin reported on the experience at the Mayo Clinic with the roentgenologic diagnosis of neoplastic lesions encountered up to and including the year 1939. By then 17 instances of duodenal neoplasm had been encountered in which roentgenologic examinations of the duodenum were recorded.

The existence of a lesion and its site were correctly predicted in all but 2 of the cases, although the precise diagnosis of neoplasm was offered in only 9 of them.

Since 1939, 20 cases of duodenal neoplasm have been encountered. In every instance the existence of the lesion and its location were correctly predicted at the roentgenologic examination. In 12 of the cases the roentgenologic diagnosis of neoplasm was later established at pathologic examination of the tissue (Fig. 2). In a single case of leiomyosarcoma of the third portion of the duodenum the roentgenologic diagnosis was ulcerating leiomyoma (Fig. 3). In 7 cases the roentgenologic diagnosis was given in such expressions as "lesion," "filling defect," "polypoid lesion," "intrinsic lesion," and "crescentic defect." Although not ideally precise, terms such as these have a connotation of neoplasm and so are considered to be satisfactory; a roentgenologic diagnosis can hardly be expected to be more precise than a gross pathologic one.

Tumors and other lesions of structures in close anatomic proximity to the duodenum sometimes extend to it and involve it segmentally, producing a roentgenologic picture similar in many respects to that produced by primary duodenal neoplasms. Cysts and tumors of the pancreas are especially prone to do this but tumors of the common duct near the ampulla of Vater, of the hepatic flexure of the colon, and of the retroperitoneal lymph nodes (Fig. 4) have also been known to simulate the roentgenologic picture of primary duodenal

lesions very closely. Evidence of the essentially extraduodenal nature of such processes is usually elicitable at roentgenoscopic examination, for such lesions tend to be large, and careful palpation almost always gives the clue to the correct diagnosis.

Obstructed hollow viscera are notoriously difficult to work with roentgenologically and the higher the degree of obstruction, the more difficult it is to determine the precise pathologic nature of the obstructing process at roentgenologic examination. Obstructing lesions of the duodenum are not exceptions, especially when the obstruction is encountered at or just below the pyloric ring. In this situation the roentgenologic evidence for neoplasm must be well developed, indeed, if a diagnosis of neoplasm is to be entertained, for in all age groups benign duodenal ulcer is overwhelmingly more often the cause of obstruction at this level than are neoplastic processes (Fig. 5). On the other hand, nonneoplastic obstructing lesions, intrinsic in the duodenum, are encountered comparatively rarely in the second and third portions of the duodenum. Therefore, it is expedient to consider neoplasm as a diagnostic possibility whenever obstruction is roentgenologically demonstrated to exist at these levels (Fig. 6).

Obstruction of all degrees was observed in this series of cases, the amount of gastric contents retained varying from 200 to 1,400 cubic centimeters. Efforts at reducing the amount of gastric retention by repeated gastric lavage fail as a rule to facilitate satisfactory roentgenologic examination, no matter what the cause of retention may be or where this cause may be located. The roentgenologic examination is hindered as much by the presence of gastric secretion as it is by the gastric dilatation. It seems that the mere act of passing the stomach tube increases the flow of gastric secretion in most cases and days rather than hours are consumed in reducing the size of a stomach dilated as a result of chronic obstruction. For this reason, operation is usually recommended as soon as the fact of chronic obstruction is established, because in the great majority of instances surgical intervention will become necessary no matter what the cause of obstruction may prove to be.

The roentgenologic criteria for the diagnosis of neoplasm of the duodenum are identical with those used in the diagnosis of such lesions in other tubular portions of the gastrointestinal tract. They have been adequately described in other publications and we have no additional data along these lines to describe.

At this point we wish to repeat a warning about the administration of barium by mouth to patients presenting symptoms of intestinal obstruction. When the obstruction is high in the duodenum, the clinical picture is clear enough to make the procedure safe. But lesions near the duodenojejunal juncture may present a clinical picture in which a lesion of the lower part of the intestine must be considered. In such cases it is wise to proceed with caution and aspirate the stomach and duodenum. A lesion of the colon should be ruled out before proceeding with the standard roentgenologic examination of the small intestine. Serious consequences have often followed the injudicious administration of barium by mouth to a patient who had a lesion of the lower part of the intestine. In such cases partial obstruction may be converted to total obstruction by barium.

SURGICAL ASPECTS

Up to 1935, unless a segmental resection in the first or third part or local excision was possible, lesions of the duodenum were not considered removable. Experience with resection of the pancreas and duodenum has changed the attitude, and radical resections are now possible. While it may not be possible to remove the node-bearing tissue of the periaortic chain, local extension on the surface of the pancreas can be removed by partial pancreatectomy. Applicable operative procedures, designed primarily for the treatment of pancreatic and vaterian lesions, have been discussed repeatedly by Whipple, Brunschwig, and Hunt.

It is difficult to assign credit for the greater present-day success in radical pancreatoduodenectomy to any single advance in surgery. Relatively little is known of the physiology of the duodenum. Even the fundamental functions of its cells are not clearly established. But it appears that men and animals can get along without a duodenum (7). On the other hand, the physiology of the pancreas has been the subject of careful study for a century. Early removals of part or all of the pancreas were performed with some knowledge of the disturbances created. Improved knowledge of the control of the electrolytes of the blood, the use of vitamin K, the availability of bank blood and plasma, the preoperative and postoperative administration of vitamins, carbohydrates and proteins to bolster the liver, chemotherapy and antibiotics have each played its rôle, so that a procedure that was impossible for the masters of the previous generation is within the scope of the young surgeon of today.

There is great variation of the individual requirement for the external secretion of the pancreas. Results obtained in animals cannot be applied directly. The necessity of anastomosing the ducts of a partially removed pancreas to the jejunum remains to be evaluated. The various methods for re-establishing the flow of pancreatic juice add materially to the risk of the operation. While it is the opinion of many surgeons that the flow of pancreatic juice is important, if not essential, we have encountered cases in which the patient did well after total pancreatectomy or partial pancreatectomy with ligation of the stump. In fact, some of these patients did well even without the oral ingestion of pancreatin. Furthermore, we have no knowledge of how long the pancreatic external secretion effectively continues after such anastomosis. Answers to these and other problems will be found only after larger numbers of cases in which radical pancreatoduodenectomy has been performed are available for study. When it is necessary to remove the entire pancreas, replacement of insulin is not difficult but the requirement of lipocaine, choline, or other factors in prevention of hepatic damage and infiltration with fat after long periods of survival must be evaluated for human beings.

There are manifold technical problems which arise during the performance of radical pancreatoduodenectomy. Many of these are concerned with the method of handling the common duct. In cases of duodenal ulcer with cicatricial stenosis and in those of carcinoma of the pancreas, ampulla, or first or second part of the duodenum, along with shortening of the duodenum, there is often a shortening of the common duct. This tends to draw on the fork produced by the juncture of the cystic and hepatic ducts so that the angle is reduced and the two ducts are fused side by side. We have encountered several cases in which use of the gall bladder for anastomosis was contemplated but in which, after ligation of what was believed to be the common duct, the surgeon found that in reality he was clamping the cystic and common ducts. These two ducts may run side by side to a point close to the duodenum. Thus a previously made cholecystenteric stoma, while it relieves biliary obstruction, may have to be disconnected during pancreatoduodenectomy because it is in the way and because when the common duct is tied, unless a probe is passed, there is no way of being sure how far the bifurcation is from the ligature.

In the performance of a palliative anastomosis of the gall bladder to the intestinal tract there are many advantages to cholecystojejunostomy for

lesions in the region of the ampulla. If the gall bladder is anastomosed to the stomach and the patient survives for some time, the lesion may go on to obstruct the duodenum and the biliary flow will add to the vomitus. Hence it is better to anastomose the gall bladder to the jejunum than to the stomach. In 3 of the cases in this series, palliative cholecystenterostomy was followed by a subsequent palliative gastroenterostomy because the patient lived long enough to have duodenal obstruction.

Preoperative measures. So many vital functions are disturbed by lesions in the duodenum that extensive physiologic readjustments are necessary. Imbalance of electrolytes requires the intravenous or subcutaneous administration of sodium chloride and calcium. Anemia or hypoproteinemia makes blood transfusions essential. Determinations of prothrombin must be made to evaluate the need for vitamin K. Hepatic reserves must be bolstered by administration of carbohydrates and proteins. Intravenous administration of glucose is usually necessary to increase hepatic glycogen. Dilatation of the stomach must be reduced by repeated lavage.

During radical resections, which frequently involve more than 3 hours of operating time, intravenous administration of fluids is obligatory. In addition, the average patient requires at least 1,500 cubic centimeters of blood during and after the operation. Five to 8 grams of sulfathiazole should be dusted intraperitoneally. After radical resection it is usually wise to place the patient in an oxygen tent, administer blood, and maintain adequate blood levels of sulfadiazine and penicillin. Vitamin K should be added to the intravenously administered fluids, since biliary flow may be obstructed by edema.

REPORT OF A CASE

The following case illustrates some of the points stressed in this study.

The patient was a white woman 52 years of age. During the first week of January, 1943, she noted the sudden onset of a dull pain in the epigastrium "as if a lump was there." Belching and sour eructations were prominent. A week later she became jaundiced and pruritus was severe. Her appetite was good. It was believed that she had obstructive jaundice due to carcinoma of the pancreas. Severe hyperlipemia was present.

On February 3, 1943, cholecystogastrostomy was performed. The common duct and the gall bladder were dilated and a nodular mass was noted in the region of the pancreas. Biopsy of the liver revealed advanced infiltration with fat and cholangitis.

The patient was well for 1 year and then began to have severe epigastric pain, belching, and bloating. Her appetite was good but she lost 25 pounds (11.3 kgm.). At examination in January, 1945, there was no jaundice. The concen-

tration of hemoglobin was 8 grams per 100 cubic centimeters of blood and erythrocytes numbered 4,390,000 per cubic millimeter of blood. Analysis of gastric contents revealed anacidity. Roentgenologic examination of the stomach and duodenum revealed an obstructing lesion of the second portion of the duodenum with dilatation of the stomach and duodenum proximal to it.

On January 13, 1945, operation was performed. The entire duodenum, about 30 centimeters of jejunum and about two-thirds of the pancreas were removed. The cholecystogastric stoma was disconnected and choledochojejunostomy was performed. Half of the stomach was resected and gastroyejunostomy (posterior Pólya) was performed. During the procedure great difficulty was encountered in dissecting the pancreas free from the portal vein. Three small openings were made in the portal vein, and these were closed with fine silk. Figure 9 gives a rough diagrammatic approximation of the arrangement before and after operation. The shaded area depicts the region removed *en bloc*. The stump of the pancreas was closed by three catgut mattress sutures and left free in the peritoneal cavity. Passing from the patient's right to left the jejunum first received the biliary duct. The latter was represented by the biphate cystic duct and hepatic duct, which looked like a single tube externally. Both were anastomosed end-to-side to the jejunum. The site of the previous anastomosis of the gall bladder to the stomach was sutured. The entire shortened common duct was found to have been removed with the specimen. The gastroyejunal stoma was made distal to the hepatoyejunal stoma and the jejunum was sutured to the mesocolon at the site of the former ligament of Treitz.

The tumor was an adenocarcinoma of the duodenum, grade 1 (Broders' method), without involvement of lymph nodes (Figs. 7 and 8). The postoperative course was uneventful. For a short time the patient was mildly diabetic with a fasting concentration of sugar of 145 milligrams per 100 cubic centimeters of blood. She required 15 tablets of pancreatin (Wilson) three times a day to give her one or two solid stools a day. There was slight drainage from the incision for 3 weeks. When she was examined 6 months later, her blood was normal. She had gained 7 pounds (3.2 kgm.). There was no evidence of diabetes. She was well at the time when this paper was written—8 months after resection and 32 months after the lesion had been identified and considered inoperable at the first operation.

ANALYSIS OF OPERATIVE CASES

1. Combined duodenectomy, partial pancreatectomy, partial gastrectomy, partial choledochectomy and choledochojejunostomy was performed four times. There was 1 death in the hospital (25 per cent), which resulted from repeated gastric hemorrhages. The results in this group cannot be evaluated since the other 3 patients were alive when this paper was written 1 year, 7 months, and 3 months after operation.
2. Segmental duodenal resection with or without partial gastrectomy was performed four times with one death in the hospital (25 per cent). Here again the death was due to hemorrhage. Of the other patients, 1 died within 2 years while the remaining 2 were alive when this paper was written, 1 and 4 years after operation was performed.

3. Local excision was done in 1 case. The patient was alive 4 years after operation.

The remaining operations were palliative.

4. Posterior gastroenterostomy was performed twenty times with 4 deaths in the hospital (20 per cent). These patients were in very poor condition. In 2 instances the patients were unconscious as a result of gastric tetany and the operation was of an emergency nature. The surviving patients demonstrate that the lesion is frequently slow in progress when the obstruction is relieved. No doubt in some of the cases resection would have been performed if the patients had been seen recently. The average period of survival for this palliative procedure was 21 months, with 4 patients living 7, 6, 3, and 2½ years after the gastroenterostomy to account for the high figure.

5. Anterior gastroenterostomy was performed three times with no deaths in the hospital. One patient died in 1 year and another in 3 months. The third patient could not be located.

6. Duodenojejunostomy was performed three times with 1 death in the hospital (33 per cent). One patient died in 3 years and the other in 3 months.

7. Cholecystostomy was performed twice with 1 death in the hospital (50 per cent). The survivor died 7½ months after operation.

Thus there were 8 deaths in the hospital in 37 procedures—a mortality rate of 22 per cent.

8. Exploration only was done eight times with 4 deaths in the hospital (50 per cent). The average period of survival in the 4 cases was 5½ months.

In reading the literature on carcinoma of the duodenum one gets the impression that the prognosis is very bad. However, most of the reported cases are taken from necropsy records. On the other hand, from the surgical cases presented here, one gets the impression that when radical duodenectomy is well established the results in cases of this rare lesion will be better. In the case presented earlier in this paper the lesion was resectable 2 years after it had been identified at a previous operation. While, in general, extension into the local nodes seems to occur relatively early, there is a long latent period before the lesion extends to distant sites such as the liver or lungs. The prognosis for lesions of the duodenum is better than for lesions of the jejunum or ileum. This may be explained by the proximity of the lesions of the duodenum to the stomach and the inclusion of two important ducts in the region, which tend to produce symptoms earlier. It is true despite the greater apparent ease of removal of lesions of the jejunum and ileum.

In the collected series in the literature it is stated that postoperatively the prognosis of lesions of the first and second parts of the duodenum is very poor. In this series 1 patient was alive when this paper was written, 6 years after resection of a lesion of the first part of the duodenum and another died 7 years after gastroenterostomy, at which time the lesion was confirmed by necropsy. In lesions of the third part of the duodenum the results are not as good, with only 2 patients alive 2 years after operation.

SUMMARY

Forty-nine cases of malignant lesions of the duodenum, exclusive of lesions of the papilla of Vater, are analyzed. Obstructive features were prominent in 38 while in 6 cases anemia resulting from loss of blood was the chief finding. In 45 cases operation was performed. Radical resection was done in 4 cases, segmental resection in 4, and local excision in 1. The operative mortality rate in cases in which procedures other than exploration were performed (37 cases) was 22 per cent.

gluteal fascia was first brought to my attention at the Mare Island Naval Hospital, in 1942, by Commander Charles E. Pope, then in charge of these cases. Miscall and Holder and F. C. Shute *et al.* have also described the use of the gluteal fascia but in a manner that entails approximation of these tissues under greater tension than the Pope procedure.

In the utilization of the gluteal fascia, certain details of management and technique have developed which are considered most important in achieving a successful primary closure:

1. As little trauma as possible is inflicted on all tissues. Even retractors are not used, so as to avoid injuring the delicate fat cells lining the wound.

2. Contrary to almost universal advice in recent articles, clamps on bleeding vessels are rigidly avoided! Patience and local digital pressure usually suffice to stop the bleeding, and rarely is it necessary to place any ligatures on bleeding arteries regardless of the forceful bleeding that follows the initial incisions, thereby reducing greatly the dead and traumatized tissue as well as the amount of foreign material left in the wound to interfere with healing. Our experiences with bleeding from divided arteries in this area substantiate the observation that a completely divided artery usually retracts into the tissues followed by cessation of bleeding. Frequently when bleeding persists, close inspection reveals that a tangential wound of an artery has been produced or a branch has been severed at a point flush with its emergence from the parent artery. An incision completely severing the artery at point of bleeding results in prompt cessation of bleeding.

Following excision *en bloc* of the diseased tissue the wound is packed lightly with gauze while the operator carefully explores the sinus tracts with a probe to determine if by chance any tract has been cut across leaving behind epithelial elements. If such oversight has occurred, wider excision is performed.

3. The interrupted sutures of No. 0 chromic catgut (Fig. 4A) approximating the fascia are minimal in number (4 to 8). The use of nonabsorbable sutures in this area was reluctantly abandoned after we had been compelled on a number of occasions to operate for the removal of buried sutures of cotton, silk, or wire placed there by others or by us. These sutures in the gluteal fascia serve also to bring together the overlying fat, so that no devitalizing and traumatizing sutures are applied in the subcutaneous fat. There are only two layers of suture: one approximating

the gluteal musculofascial flaps and one closing the skin (Fig. 4C).

4. The skin is approximated by a special continuous subcuticular stitch of dermol or wire applied 2 to 3 millimeter within the epithelial edge (Fig. 4B). The two ends of the dermol protrude from the wound at either end without any tying of knots. Frequently, the length of the incision requires that 2 such continuous sutures be applied (Fig. 5C) which are not withdrawn until the 7th or 8th day. The use of the subcuticular stitch which is considered a most important detail avoids passing sutures through infected skin into vulnerable fat. Skin sutures in this area, if left in place for several days, show redness and inflammation around each stitch hole, indicating that bacterial organisms are present which could easily penetrate the deeper tissues and infect the wound.

5. No drains should ever be used in this area, but the superior or posterior end of the wound is not closed for about 2.0 centimeters so as to provide an escape for tissue fluid or blood. At first the skin at the inferior or anterior end of the wound was incompletely closed but experience early taught us that the skin in the gluteal fold must be approximated very carefully—epithelial edge to epithelial edge—otherwise a small granulating wound remains in the gluteal cleft which heals poorly because of heat, moisture, and motion. As previously stated, this delayed and prolonged healing deep in the gluteal fold may produce a dimpling or downgrowth of epithelial elements below the level of surrounding skin—a factor which may favor the penetration of hairs into subcutaneous areas and the recurrence of infection. The wound is dressed with gauze moistened with tincture of merthiolate or zephiran solution so as to inhibit bacterial growth if later soaked with blood. To relieve tension from the sutures approximating the gluteal fascia, the two buttocks are securely strapped and pulled together with long adhesive strips. The wound is not dressed for 7 to 8 days. If bleeding occurs sufficiently for blood to escape the gauze dressings during the first 24 hours, the original dressing is not removed but is simply reinforced with additional gauze placed over it. An order to that effect is left with the nurse.

6. Chemotherapy is utilized before, at, and after operation. For 24 hours preceding the operation, penicillin is administered in optimum dosage (20,000 units intramuscularly every 3 hours), plus sulfadiazine and sodium bicarbonate, 1 gram each, every 4 hours orally; at intervals during the operation, sulfanilamide is smeared into all nooks, crannies, and crevices of the wound (3), and the

Fig. 1. a, Patient with subcutaneous abscess and eleven midline dimples. b, Nest of hairs completely surrounded by bone of the coccyx necessitating coccygectomy for complete removal of the pilonidal elements. Failure to recognize such deep penetration of hairs undoubtedly is responsible for some recurrences.

newly created raw surfaces are moistened with penicillin solution—(50,000 units in 25 c.c. water; the balance of 50,000 units is administered intravenously). After operation the administration of penicillin and sulfadiazine is continued as described for 4 or 5 days.

7. The patient is returned to his bed with specific instructions: He may lie on his abdomen or on his side and may stand to void, but he may not lie on his back nor may he sit. He is confined to bed except for lavatory privileges.

8. A nonresidual diet is imposed for 7 to 8 days, thus reducing the need of bowel movements to a minimum.

9. Even though healing is complete in 10 days to 2 weeks' time, military personnel are not returned to full duty under 4 to 6 weeks, in order not to jeopardize the final result in any way. An occasional sequel of the operation is a temporary numbness of the midline skin due to division or to temporary physiological block of subcutaneous nerve fibers incident to the mobilization of the gluteal fascia. This is usually not a subject for complaint, and gradually disappears.

When large subcutaneous abscesses have burrowed their way over the upper sacrum, the procedure described must be modified. The gluteal fascia is mobilized as here described to cover the coccygeal and lower sacral area. Over the upper sacral area where healing more readily occurs and where raw areas are not subjected to factors inhibiting healing as in the deep gluteal folds, the skin flaps are tacked down directly to the pre-sacral fascia (5) by interrupted sutures of fine catgut including a bite of the fascia and a bite of

Fig. 4. A, Approximation of musculo-fascial flaps by four to eight interrupted chromic catgut No. 6, including also a bite in the midline of the pre-coccygeal or presacral fascia, thus insuring obliteration of the dreaded dead space. B, Approximation of skin is effected by continuous subcu-

ticular sutures of dermol or steel which are not tied, and which after 8 to 10 days are completely withdrawn from the wound. The skin in the posterior 2 centimeters of the wound is not closed by sutures but is left open for the escape of blood and serum. C, Only two layers of sutures are necessary—one in the gluteal fascia which also approximates the fat, and a second layer in the subcutaneous tissue.

subcutaneous tissue about 1.5 centimeters lateral to the skin edges. The skin edges may or may not be approximated by a subcuticular stitch of continuous dermol, leaving the superior 1.5 to 2.0 centimeters of the wound open. When the skin is not closed, there is usually only a small granulating area present as in the MacFee procedure which heals in a short time. Occasionally, the subcutaneous hair-containing abscess cavity extends anteriorly from the coccyx to a point lateral to the anus. After excision this lateral wound may be left either open or closed primarily.

When this method of closure fails, the wound is converted into an open one and treated as previously described for open wounds in this area. Despite failure of primary union it has been observed that the mobilization of the gluteal fascia permits more rapid cicatricial contracture of the

wound, and healing is not as prolonged as in the usual excision *en bloc* and open method of treatment.

As experiences with the method described have led to such modifications as the elimination of skin-penetrating sutures, the use of the subcuticular stitch, and the local and systemic administration of sulfonamides and penicillin, failures have definitely decreased. In the last 46 cases there have been 5 failures, 2 due to hematomas which required evacuation, resulting in delayed but not prolonged healing, and 3 due to infection, one with a pyocyanus infection that did not yield to penicillin and sulfa therapy, and one whose sinus involved the margin of the anus. It should be freely admitted that in the search for a dependable treatment of pilonidal cysts and sinuses, the methods used by many operators have been found successful some times, even

Fig. 5. a, Postoperative appearance in patient 1 on 10th day. b, Postoperative appearance in patient 2 on 12th day. c, Postoperative appearance in patient 3 on 7th day before removal of two dermal continuous sutures; the protruding suture is cut off at one end and pulled out of tissues by traction on other end. many times, but failures annoyingly recurred. It may be that careful attention to certain details, which to some may seem minor, will assist in the attainment of the perfection that we seek. It is confidently asserted that in the treatment of this lesion by primary closure, the attention to such minor details is often the determining factor between success or failure.

SUMMARY

Among military personnel, pilonidal cysts and sinuses have provided a problem of major importance. Following the block dissection—open wound treatment, healing and convalescence are prolonged, and recurrence remains an annoying problem.

There are four factors inherent in the lower sacral and coccygeal area which interfere with proper healing, and are conducive to prolonged and ill controlled infection, namely, moisture, heat, motion, and trauma. In the postoperative care of open wounds following block dissection, the following points are stressed: (1) rest in bed, (2) spread rather than approximation of buttocks

accompanied by exposure of wound to sunlight or Quartz lamp radiation, and (3) instructions forbidding walking, sitting or lying supine until the wound is healed.

The re-establishment of typical midline dimples in the line of scar following block excision suggests that this lesion may be acquired as well as congenital in origin. Downgrowth of epithelium below skin level and penetration of deeper tissues by growing hairs during the prolonged healing process may be the cause of such recurrences.

In attempts at excision and primary closure, the greatest stumbling block to good healing is the dead space between skin and sacral and coccygeal fascia.

The most dependable method of primary closure utilizes gluteal muscle-fascia flaps according to the method of Pope, rather than subcutaneous fat to fill in this dead space. Following their mobilization for several centimeters lateral to each lateral edge of the coccyx and lower sacrum, the gluteal musculofascial flaps are approximated in midline by a minimal number of chromic catgut No. 6 sutures including also a bite of the pre-

coccygeal and presacral fascia in its lower half. The skin is approximated by 1 or 2 continuous subcuticular stitches of dermol or steel wire which are removed in 7 to 8 days. The skin is left open for 2 centimeters at its upper or posterior end to permit escape of wound fluid and blood. Drains into the wound must *not* be used.

Chemotherapy including administration of penicillin and sulfadiazine is utilized before, at, and after operation.

Operation is performed with the least possible trauma to tissues: Blood vessels are not crushed, clamped, nor tied in order to reduce to a minimum foreign material and dead tissue in the wound. Fat is not devitalized by encircling sutures. The

less trauma produced in the wound, the better healing and the less infection there will be in this highly vulnerable area.

THE USE OF PENICILLIN THERAPY IN CONJUNCTION WITH FREE BONE GRAFTING IN INFECTED AREAS

LEROY C. ABBOTT, M.D., F.A.C.S., FREDERIC C. BOST, M.D., F.A.C.S., EDWIN R. SCHOTT-
STAEDT, M.D., WALTER E. STERN, M.D., and HORACE J. McCORKLE, M.D., F.A.C.S.,
San Francisco, California

AMONG the early favorable results obtained with the use of penicillin in the control of infections involving bone, in the University of California Surgical Services, were 2 cases of subsiding acute hematogenous osteomyelitis (hemolytic *Staphylococcus aureus*) in which there was rapid revascularization and incorporation of sequestra in the process of healing of the bone. One case was observed in which a recently infected (hemolytic *Staphylococcus aureus*) Hibb's fusion of the spine containing free iliac bone grafts healed rapidly with penicillin therapy and remained healed without loss of the grafts. These experiences suggested the possibility of bone grafting in areas in which there was chronic infection, or in recently healed contaminated bone defects.

During the past year, 8 patients with infections of the bone in which free bone grafts have been implanted into infected areas have been studied. This study is part of the contract with the Office of Scientific Research and Development for investigation into the use of penicillin in the treatment of bone infections, under the chairmanship of Dr. Howard C. Naffziger, responsible investigator, at the University of California Medical School. The work described herewith has been done in collaboration with the orthopedic surgical services of Dr. LeRoy C. Abbott. Six patients had infected fractures with nonunion that involved the tibia and fibula; one patient had an infected fracture with nonunion of the femur, and one patient had tuberculosis of the knee associated with secondary infection involving the upper end of the tibia, the lower end of the femur, and the knee joint. In all cases the infection was in a chronic or quiescent phase when treatment was undertaken. The pathogenic bacteria cultured from these cases were hemolytic *Staphylococcus aureus* in 4 cases; *Escherichia coli* and hemolytic *Staphylococcus aureus* in 1 case; and beta

hemolytic streptococcus and hemolytic *Staphylococcus aureus* in 2 cases.

Systemic penicillin treatment was given every 3 hours by the intramuscular route preoperatively in 5 cases. In 2 cases the preoperative dosage was 100,000 units per day for 4 and 6 days, respectively. Sulfathiazole was also given in one of the cases in which there was a combination of *Escherichia coli* and hemolytic *Staphylococcus aureus* in the wound. In 1 case the preoperative penicillin dosage was 150,000 units daily for 5 days; in another case 200,000 units of penicillin were given for 1 day before the bone grafting operation. One patient received 100,000 units daily for 37 days and 150,000 units for 5 days before the bone grafting operation. Three patients had no preoperative penicillin therapy.

In 5 cases the bone grafting operation was done in a field in which there were open infected draining wounds or sinuses. In the other 3 cases the grafting was done in areas in which infected wounds had closed recently. All of these patients had had previous operations and were incapacitated with an extremity that was useless because of infection or nonunion, or both. Three of these patients had previously had metal plates inserted for fixation; one of these had been plated twice. In these cases the old plates were removed before the bone graft was inserted. A wound cleaning and trimming procedure had been carried out on all the patients with compound fractures at the time of injury. A "saucerization" had been done without benefit in one case. A previous attempt at free bone grafting in conjunction with sulfa therapy had been made in one patient, but the graft was lost because of infection. The patient with the secondarily infected tuberculous knee joint had had an arthrodesis of the knee joint and a synovectomy at previous operations.

The free bone grafting operations done with penicillin therapy were: (1) insertion of iliac grafts and metal plates, 4 cases; (2) sliding bone graft and metal plating, 1 case; (3) iliac grafts without metal fixation, 2 cases; and (4) sliding graft without plating, 1 case. The bone grafting was done in patients with infected wounds or

The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development, Washington, D. C., and the University of California.

experience indicates, however, that penicillin therapy makes it possible to obtain successful free bone grafting directly in bone defects infected with organisms susceptible to penicillin in which it may be undesirable to wait for preliminary healing. The use of metal devices for internal fixation may be necessary in some of these cases, but they should probably be avoided in contaminated areas unless they are absolutely indispensable to maintain fixation and position. If they are used, it may be desirable or even necessary to remove them after firm union of the bone has been obtained.

In cases in which free bone grafting is done in a contaminated area, penicillin therapy should be regulated with bacteriological studies, including identification of the bacterial flora of the wounds, with frequent cultures and tests for sensitivity of the organisms to penicillin. The presence of penicillin-resistant nonpathogenic organisms has not interfered with free bone grafting in a contaminated bone defect, provided the pathogenic organisms were sensitive to penicillin; however, penicillin-resistant organisms often delay healing in open wounds in the overlying soft tissues.

In cases of bone grafting, the systemic penicillin therapy has been given intramuscularly at 3 hour intervals. It is probably safest to precede the bone grafting operation by at least 3 to 7 days of systemic penicillin therapy. Experience with such cases as well, as with the treatment of other infections of the bone, indicates that postoperative treatment with penicillin should be prolonged for several weeks—usually from 3 to 8 weeks, depending somewhat on the type of organism, the amount of contamination, and the size of the area that must become revascularized during the period of healing after infection is controlled. The dosage of penicillin also varies somewhat with these conditions and should probably be at least 100,000 units daily under the most favorable circumstances, and up to 200,000 units daily, or more, in others. Where the contaminated area is accessible to local penicillin therapy, it appears desirable to instill from 5,000 to 30,000 units daily through a small soft rubber tube, for 7 to 14 days postoperatively. The strictest asepsis should be practiced in handling and injecting the penicillin solution into the tubes. They should probably be removed from the wound by at least the 14th postoperative day, by making a small circular opening in the cast around the tubes. All secondary operations, such as those for delayed closure, removal of plates, or skin grafting, should be accompanied by systemic penicillin therapy for several days before and after the operation.

Primary closure of the soft parts over the grafted bone defect is most desirable. It is reasonably safe and practical if cultures reveal the absence of penicillin-resistant pathogenic bacteria and if it can be accomplished without tension. Primary closure around a small soft rubber tube through which supplementary penicillin is given is even more advantageous when this is technically possible. The presence of penicillin-resistant nonpathogenic organisms does not ordinarily prevent closure and healing, but such bacteria may contribute to the delay in healing of open wounds in the soft tissues. Following operations in areas in which there are penicillin-resistant, potentially pathogenic organisms such as proteus, the wound in the soft parts should always be left open and secondary closure done several days later. In other cases, extensive soft tissue defects may necessitate skin grafting. In all cases in which delayed closure after bone grafting is necessary, it is essential that the wound be protected from contamination from external sources. Such areas should be dressed infrequently and with the strictest aseptic precautions.

Following are summaries prepared from the records of these cases:

CASE 1. A man, aged 43, had a fracture of the tibia for which an open reduction, followed by insertion of metal plates, was performed. The wound became infected and drained for 7 months before he entered the hospital in June, 1944, for penicillin treatment. The fracture site was not united. Bacterial cultures from the wound grew *Escherichia coli* and hemolytic *Staphylococcus aureus*. He received 100,000 units of penicillin intramuscularly daily for 2 days before operation, together with sulfathiazole. The first operation under penicillin therapy consisted of removal of the old metal plate, excision of sinuses and infected scar tissue. The wound was closed without drainage. Postoperatively 100,000 units of penicillin were given daily for 21 days, and sulfathiazole treatment was also continued for this period. The wound apparently healed *per primam*, but 8 days after the administration of penicillin was discontinued, a small area of infection developed and the drainage again contained *Escherichia coli* and hemolytic *Staphylococcus aureus*. A second course of penicillin, 100,000 units daily for 15 days, without sulfa therapy, was given and the wound healed promptly and remained healed. The patient was discharged with plaster fixation for 2 months, after which he returned to the hospital on August 10, 1944, for a bone grafting operation. The wound had remained healed, but there was nonunion at the fracture site. Preoperatively penicillin was administered at the dosage of 100,000 units daily for 4 days. The operation consisted of insertion of a free iliac bone graft with metal plate fixation at the site of the nonunited fracture of the tibia. Postoperatively 100,000 units of penicillin were given daily for 7 weeks. The wound through which the bone grafting was done healed *per primam* and remained healed. However, the old sinus tract was opened during the manipulation and it began to drain on the 16th postoperative day. Cultures grew *Escherichia coli* and beta

Fig. 1. Case 5. X-ray appearance of left knee of patient with tuberculous secondarily infected with hemolytic *Staphylococcus aureus*.

Fig. 2. Case 5. Condition present 3 months after excision of infected joint and insertion of bone grafts under penicillin therapy.

hemolytic streptococcus and diphtheroids. This wound closed gradually and was completely healed by the 26th postoperative day. The patient left the hospital on crutches, with the extremity in plaster, 55 days after entry for the bone grafting operation. His most recent follow up visit was on February 6, 1945. The wound has remained healed and there is no motion at the fracture site. Roentgenograms show evidence of repair of the fracture site. At present this patient has full weight bearing with out support.

CASE 2. A man, aged 45 years, had an infected fracture of the femur with nonunion of 3 years' duration. There had been 2 unsuccessful attempts at internal fixation with metal plates. He entered the hospital for penicillin treatment on July 10, 1944. Hemolytic *Staphylococcus aureus* and *Streptococcus viridans* were cultured from the sinuses that drained from the ununited fracture site. He was

given 200,000 units of penicillin preoperatively for 1 day. The operation consisted of removal of the old metal plate, excision of sinus tracts, scar and nonviable bone, and insertion of a free iliac bone graft and new metal plates. The wound was closed without drainage. Postoperatively the patient was given 200,000 units of penicillin for 1 day and 100,000 units daily for 17 days. The wound healed *per primam*, and he was discharged with crutches and a brace a brace, after 3 months' hospitalization.

Six months after his operation he developed a small draining sinus from which anaerobic streptococci were cultured. At present he has firm union, and he has reentered the hospital for another course of penicillin therapy and possibly removal of the metal plates.

CASE 3. A man, aged 37 years, had a compound fracture of the tibia and fibula 3½ years ago, with chronic infection following an operation for internal fixation with metal plates. Subsequently the plates were removed and a "saucerization" performed and sulfathiazole therapy given, but the wound continued to drain. The patient entered the hospital for penicillin treatment on July 29, 1944, with nonunion of the fractures and an open, granulating wound from which hemolytic *Staphylococcus aureus* was cultured. Preoperatively 200,000 units of penicillin were given daily for 6 days. At operation, the sinuses, granulations, and infected scar tissues were removed, and a free iliac bone graft and metal plates were inserted. The wound was closed. Postoperatively 200,000 units of penicillin were administered daily for 47 days. The wound developed necrosis followed by a low grade infection due to tension and too great undermining of skin flaps at the site of closure. After the wound became clean, bacteriostasis was maintained with penicillin in ointment applied locally for 60 days. On December 15, 1944, the metal plates were removed, and the bone graft was observed to be well and securely fixed in its position, and well vascularized. The patient received 200,000 units of penicillin daily for 60 days following this procedure. The open wound was covered with an intermediate thickness skin graft on January 14, 1945. The patient left the hospital on June 20, 1945, ambulatory, with an actual weight bearing brace. Apparently he has firm union at the bone grafted fracture site and the skin is healed.

Fig. 3. Case 6. Six months after excision of infected knee joint and bone grafting under penicillin therapy. Wound healed *per primam*. Patient ambulatory with a stable knee joint.

4 cases, beta hemolytic streptococcus and hemolytic *Staphylococcus aureus* 2 cases, *Escherichia coli* and hemolytic *Staphylococcus aureus* 1 case, and *Streptococcus viridans* and hemolytic *Staphylococcus albus* 1 case. Systemic penicillin was given intramuscularly at 3 hour intervals before operations in 5 of the cases, and after operations in all of the cases. The dosage varied from 100,000 to 200,000 units per day. Prolonged treatment extending over many weeks was necessary. The total amount of penicillin used in each of these cases varied from 3 to 8 million units.

The free bone grafting operations consisted of insertion of iliac grafts and metal plates, 4 cases; sliding bone graft and metal plates, 1 case; iliac grafts without metal fixation, 2 cases; and sliding bone graft without metal plating, 1 case. The operative wounds were closed completely in 7 cases and in 1 case the wound was closed around a small soft rubber tube through which supplementary treatment with local penicillin was given. The most recent bone grafting operation was done 3 months ago and this wound has not yet been inspected, but there are no signs of infection and the patient has left the hospital with plaster fixation. Immediate primary healing has resulted in 4 cases; however, in 1 of these cases an adjacent sinus tract reopened following the operation and drained temporarily, and another patient returned for treatment of an infection that developed 6 months after operation. Two wounds developed necrosis and low grade infection resulting from tension at the site of closure, and these have required secondary closure and skin grafting procedures. One wound became infected

and required drainage, but the patient was receiving inadequate doses of penicillin at the time.

At present the wounds of 6 of the 7 patients with grafting operations for infected nonunited fractures are healed completely, and 1 (which became infected 6 months after operation) is under treatment. By x-ray examination the bone grafts in all of these cases appear to be viable and in proper position, but 1 graft in a defect of the tibia fractured 4 months after operation and required a supplementary (fibular transplant) procedure. None of the grafts has sequestered, extruded, or been absorbed. Four patients have firm union of the fracture sites with metal plates still in position, and 2 have firm union without metal plates. One patient has not yet had the original plaster dressing removed, and the remaining patient is the one in which fibular transplant was required because the graft in the tibial defect fractured 4 months after the bone grafting operation.

Even though it has been possible under penicillin therapy to accomplish free bone grafting directly into the infected bone defects successfully in these cases, it is probably more desirable in most instances to attempt to obtain healing preliminary to the grafting procedure by penicillin therapy and, if necessary, operations for removal of sinus tracts, infected granulations, scar, and nonviable bone. The bone grafting may then be accomplished at a later operation in a relatively cleaner field. Adequate dosage with penicillin is a useful adjunct in all such cases in which bone grafting and other operations are done in areas in which there are bone defects infected with penicillin-susceptible organisms.

THE STRUCTURE OF THE CALCANEAL TENDON (OF ACHILLES) IN RELATION TO ORTHOPEDIC SURGERY

With Additional Observations on the Plantaris Muscle

ERWIN J. CUMMINS, M.D., BARRY J. ANSON, Ph.D., (Med. Sci.),
BRADLEY W. CARR, M.D., and ROBERT R. WRIGHT, M.D., Chicago, Illinois
With Surgical Commentary by EMIL D. W. HAUSER, M.D., F.A.C.S.

IN connection with surgical procedures designed to lengthen the calcaneal tendon, a knowledge of the constituents of the tendon is of fundamental importance. The manner in which the several contributing divisions of the entire tendon terminate—on the os calcis directly, or as elements without direct insertion into bone—determines the point and direction at which partial transection should be carried out; the local breadth of each band is equally important, because upon this dimension depends the width of the incision necessary to allow the required degree of “slipping.”

MATERIAL AND METHODS

In the present study observations were upon one hundred specimens of calcaneal tendon, 83 of them in adult cadavers and 17 in adult individuals studied immediately postmortem. From two selected specimens detailed drawings were prepared, of posterior and anterior aspects (Figs. 1 and 2). Specimen A (Fig. 1, a to e) was dissected in such a way that the fascicular structure of the tendon was emphasized; specimen B (Fig. 2, a to c) illustrates particularly the two major and the accessory components of the common tendon of insertion. The data on relationship between the gastrocnemius and soleus components of the calcaneal tendon were shown graphically (Figs. 3 and 4).

Observations on the plantaris muscle were made on 50 specimens, additive to the group of 150 previously reported from this laboratory.¹

OBSERVATIONS AND DISCUSSION

A. Anatomical Features

1. *General Description.* The superficial group of posterior crural muscles is made of three

muscles, the gastrocnemius, soleus, and plantaris. As an introduction to the authors' observations their regular anatomical features may be reviewed.²

a. *Gastrocnemius.* The ovoid heads of the gastrocnemius, which are structurally similar, take origin from facets above the femoral condyles by aponeurotic bands marginally placed on each head. These bands descend about two thirds of the way down the muscle. The fiber-bundles of the muscle pass obliquely from the supracondylar areas of origin and from the deep surface of the aponeurosis on each side to the tendon of insertion. This tendon begins as a septum between the two heads, and as a lamina on the deep surface of each head. The septum and laminae soon fuse with the broad aponeurosis which covers the dorsal surface of the underlying soleus muscle. The attachment of fiber-bundles continues to about the middle of the back of the leg. The medial head is the broader and thicker of the two, and it extends farther distalward than the lateral head.

b. *Soleus.* The heads of origin of the soleus take origin from the following: the dorsum of the proximal extremity of the fibula and the upper third of the posterior surface of the latter's shaft; the intermuscular septum between the soleus and the peroneus longus and the transverse septum over the distal margin of the popliteus muscle; the popliteal line and the middle third of the medial border of the tibia. Structurally, the fibular and tibial heads arise as broad aponeuroses which unite proximally on the deep surface of the muscle in such a way as to form a fibrous arch over the posterior tibial vessels and the tibial nerve. Continuing distally these aponeuroses diverge and grow narrow, but the fibular element is continued on the lateral side and the tibial aponeurosis on the medial side of the muscle as far as the distal quarter of the leg. The main por-

²Bardeen, C. R., in Morris' *Human Anatomy* (9th ed., p. 550).

tion of the belly of the muscle is formed by fiber-bundles which arise from the posterior surface of each of these aponeuroses; descending in an oblique course the fleshy part is inserted, in bipenniform manner, into the deep surface of the calcaneal tendon. This tendon begins as a broad aponeurosis which covers the greater part of the posterior surface of the muscle; its fibers gradually converge to form a heavy fibrous band which is inserted into the calcaneus. The fibers of the tendon are described as taking a slightly spiral course, those on the posterior surface passing from the medial margin toward the lateral surface of the calcaneus, while those on the anterior surface course in the reverse direction. The attachment of the fiber-bundles to the calcaneal tendon continues to within a short distance of the heel. A few of them arise directly from the fibula and from the posterior intermuscular septum. On the deep surface of the belly of the muscle there is an accessory fasciculus which is formed by fiber-bundles that spring on each side from the anterior surface of the aponeuroses of origin of the muscle and have a bipenniform insertion on each side of a thin, oblique tendinous lamina which inferiorly becomes united to the deep surface of the tendon of Achilles.

c. Plantaris. The plantaris arises in close association with the lateral head of the gastrocnemius. The fiber-bundles give rise to a flat, short, fusiform belly, and are united to a narrow tendon which extends along the medial edge of the tendon of Achilles toward the dorsum of the calcaneus, where it terminates in any one of several ways (see hereinafter).

2. *Variations.* There is considerable variation in the extent of the separation of the different parts of the triceps surae. The tendinous portions of the gastrocnemius and soleus may be separate almost as far downward as the heel. Either or both heads of the gastrocnemius or the soleus may be doubled. A slip from the biceps or semimembranosus of the thigh, or from the linea aspera, or from the floor of the popliteal space may join the triceps to produce a quadriceps surae muscle. On the other hand, one of the heads of the gastrocnemius or the tibial head of the soleus may be missing. A supernumerary fasciculus may extend from the deep surface of the soleus to the calcaneus. The plantaris is exceedingly variable in origin, structure, and insertion. The origin may be from the capsule of the knee-joint, the fascia of the leg, or from the tibia. None of the variations, recorded above, appeared in the present authors' series of specimens. Its tendon may terminate at almost any part of its

course in neighboring structures. It may be represented by a fibrous band. It is absent in about 7.05 per cent of cases (Daseler and Anson).

The above description of the fleshy portions of the muscles was confirmed by the authors, but more particular attention was focused on the calcaneal tendon, as made up of the tendinous portions of the gastrocnemius and soleus muscles. Most frequently the plantaris tendon is not incorporated in the calcaneal tendon; however, from the surgical aspect it must always be considered as a part of the calcaneal tendon. The tendon as a whole rotates toward the lateral side, as seen from the posterior surface (hence clockwise in the right tendon and counterclockwise in the left).

The gastrocnemius component of the calcaneal tendon begins as a broad aponeurosis at the lower margin of the muscle bellies of the two heads of the gastrocnemius muscle (Figs. 1, a and 2, a). Its fibers converge as they descend toward the insertion on the calcaneus; they rotate at the same time toward the lateral side of the soleus component. At the insertion, the gastrocnemius component not only makes up the lateral side of the posterior surface, but a portion has rotated to attain the lateral aspect of the anterior surface (Figs. 1, b and 2, c).

The soleus component is thicker than that derived from the gastrocnemius. A broad band of fibers begins high on the posterior surface of the soleus muscle and comes into apposition with the aponeurotic band of the gastrocnemius to which it is rather firmly fixed by fascial fibers. This broad band of fibers runs directly over the posterior surface of the soleus, receiving more tendinous components as it proceeds downward (Figs. 1, b and 2, c); it inserts into the medial portion of the tendon. The tendinous portion, as seen from the anterior surface, usually begins as a single band, high up in the muscular portion where it may be concealed by muscle fascicles (Fig. 1, c). This component increases gradually in size as it descends, and courses obliquely medialward (Figs. 1, b and 2, c). Portions of this anterior group of fibers appear on the posterior surface of the insertion of the tendon as a whole (making up the medial segment) (Figs. 1, a, 2, a and 2, b).

It is regularly stated that almost complete separation may be made between the components (gastrocnemius and soleus) of the calcaneal tendon. Actually, the separation cannot be made absolutely complete, since there is some exchange of smaller bands of fibers between the two (Fig. 1, c). In the experience of the present authors,

*Fibers in Fig. 1, c are of this type, are shown after separation of the components of the tendon by blunt dissection.

number and strength of fibers exchanged vary greatly; sometimes these fibers are numerous and strong enough to render complete segregation virtually impossible.

For purposes of clear description, representative fibers must be discussed separately in order to account for the several constituents of the tendon. The most lateral band (lateral accessory fasci-

culus) of the gastrocnemius (Fig. 1, a) rotates to insert on the anterolateral surface of the tendon. This band in the second specimen (Fig. 2, a and c) appears to arise from the posterior aspect of the soleus, and throughout the first half of its course is overlapped posteriorly by, and adherent to, the soleus fibers. About 1 centimeter from its origin it becomes incorporated into the gastrocnemius

tion of the belly of the muscle is formed by fiber-bundles which arise from the posterior surface of each of these aponeuroses; descending in an oblique course the fleshy part is inserted, in bipenniform manner, into the deep surface of the calcaneal tendon. This tendon begins as a broad aponeurosis which covers the greater part of the posterior surface of the muscle; its fibers gradually converge to form a heavy fibrous band which is inserted into the calcaneus. The fibers of the tendon are described as taking a slightly spiral course, those on the posterior surface passing from the medial margin toward the lateral surface of the calcaneus, while those on the anterior surface course in the reverse direction. The attachment of the fiber-bundles to the calcaneal tendon continues to within a short distance of the heel. A few of them arise directly from the fibula and from the posterior intermuscular septum. On the deep surface of the belly of the muscle there is an accessory fasciculus which is formed by fiber-bundles that spring on each side from the anterior surface of the aponeuroses of origin of the muscle and have a bipenniform insertion on each side of a thin, oblique tendinous lamina which inferiorly becomes united to the deep surface of the tendon of Achilles.

c. Plantaris. The plantaris arises in close association with the lateral head of the gastrocnemius. The fiber-bundles give rise to a flat, short, fusiform belly, and are united to a narrow tendon which extends along the medial edge of the tendon of Achilles toward the dorsum of the calcaneus, where it terminates in any one of several ways (see hereinafter).

2. Variations. There is considerable variation in the extent of the separation of the different parts of the triceps surae. The tendinous portions of the gastrocnemius and soleus may be separate almost as far downward as the heel. Either or both heads of the gastrocnemius or the soleus may be doubled. A slip from the biceps or semimembranosus of the thigh, or from the linea aspera, or from the floor of the popliteal space may join the triceps to produce a quadriceps surae muscle. On the other hand, one of the heads of the gastrocnemius or the tibial head of the soleus may be missing. A supernumerary fasciculus may extend from the deep surface of the soleus to the calcaneus. The plantaris is exceedingly variable in origin, structure, and insertion. The origin may be from the capsule of the knee-joint, the fascia of the leg, or from the tibia. None of the variations, recorded above, appeared in the present authors' series of specimens. Its tendon may terminate at almost any part of its

course in neighboring structures. It may be represented by a fibrous band. It is absent in about 7.05 per cent of cases (Daseler and Anson).

The above description of the fleshy portions of the muscles was confirmed by the authors, but more particular attention was focused on the calcaneal tendon, as made up of the tendinous portions of the gastrocnemius and soleus muscles. Most frequently the plantaris tendon is not incorporated in the calcaneal tendon; however, from the surgical aspect it must always be considered as a part of the calcaneal tendon. The tendon as a whole rotates toward the lateral side, as seen from the posterior surface (hence clockwise in the right tendon and counterclockwise in the left).

The gastrocnemius component of the calcaneal tendon begins as a broad aponeurosis at the lower margin of the muscle bellies of the two heads of the gastrocnemius muscle (Figs. 1, a and 2, a). Its fibers converge as they descend toward the insertion on the calcaneus; they rotate at the same time toward the lateral side of the soleus component. At the insertion, the gastrocnemius component not only makes up the lateral side of the posterior surface, but a portion has rotated to attain the lateral aspect of the anterior surface (Figs. 1, b and 2, c).

The soleus component is thicker than that derived from the gastrocnemius. A broad band of fibers begins high on the posterior surface of the soleus muscle and comes into apposition with the aponeurotic band of the gastrocnemius to which it is rather firmly fixed by fascial fibers. This broad band of fibers runs directly over the posterior surface of the soleus, receiving more tendinous components as it proceeds downward (Figs. 1, b and 2, c); it inserts into the medial portion of the tendon. The tendinous portion, as seen from the anterior surface, usually begins as a single band, high up in the muscular portion where it may be concealed by muscle fascicles (Fig. 1, c). This component increases gradually in size as it descends, and courses obliquely medialward (Figs. 1, b and 2, c). Portions of this anterior group of fibers appear on the posterior surface of the insertion of the tendon as a whole (making up the medial segment) (Figs. 1, a, 2, a and 2, b).

It is regularly stated that almost complete separation may be made between the components (gastrocnemius and soleus) of the calcaneal tendon. Actually, the separation cannot be made absolutely complete, since there is some exchange of smaller bands of fibers between the two (Fig. 1, c). In the experience of the present authors,

*Forn fibers in Fig. 1, c are of this type, are shown after separation of the components of the tendon by blunt dissection.

number and strength of fibers exchanged vary greatly; sometimes these fibers are numerous and strong enough to render complete segregation virtually impossible.

For purposes of clear description, representative fibers must be discussed separately in order to account for the several constituents of the tendon. The most lateral band (lateral accessory fasci-

culus) of the gastrocnemius (Fig. 1, a) rotates to insert on the anterolateral surface of the tendon. This band in the second specimen (Fig. 2, a and c) appears to arise from the posterior aspect of the soleus, and throughout the first half of its course is overlapped posteriorly by, and adherent to, the soleus fibers. About 1 centimeter from its origin it becomes incorporated into the gastrocnemius

tendon from which, however, it is separable by blunt dissection. The fasciculus courses along the lateral surface of the tendon to within 12 centimeters of its insertion, where it rotates to the anterior surface of the calcaneal tendon to fan out and occupy the lateral two thirds of the anterior surface at its calcaneal insertion. An intermediate band (Fig. 1, a), located between the two heads of the gastrocnemius, rotates to insert along the lateral margin. This band is not demonstrable in the second specimen. The most medial band (Fig. 1, a), rotates to insert at the approximate middle of the calcaneal tendon, leaving a considerable portion of the soleus exposed on the posterior surface. Here also, in the second specimen, this band appears to arise from the soleus aponeurosis, however, it soon becomes an integral part of the gastrocnemius tendon with practically no rotation of its fibers (Fig. 2, b). As a consequence, only a small portion of the soleus tendon is visible from the posterior aspect (Fig. 2, a and b). The medial fibers of the gastrocnemius component follow an almost parallel course. This band cannot be separated from the remainder of the gastrocnemius tendon as is possible in the case of the lateral band.

Examination of the deep (or anterior) surface of the tendon reveals the degree of rotation of the soleus component (Fig. 2, c), as well as the insertion of the most laterally situated band of the gastrocnemius portion (Figs. 1, b, 1, c and 2, c). The muscle fibers of the soleus extend farther distalward on the lateral side of the tendon and contribute fibers to the tendon to a point 7 centimeters from the insertion.

A thin fibrous sheath envelops the calcaneal tendon; on the deep, or anterior, aspect, the tissue contains a considerable amount of fat. This sheath is adherent to the fibula except for the distal 10 centimeters; from it originates many of the fibers of the soleus muscle. An even thinner lamina, containing almost no fat, separates the muscular portions of the gastrocnemius and soleus and contains the intervening plantaris tendon.

It is clear then, that the components of the calcaneal tendon vary considerably in size, relationship, and rotation. The length of the gastrocnemius component is the longer, varying from 26 to 11 centimeters in length, in contrast to the shorter soleus component which varies from 11 to 3 centimeters in length. The width of the tendon as a whole varies from 2.5 to 1.2 centimeters at insertion.

Rotation is such that, in the specimens examined, the gastrocnemius covers almost entire posterior aspect in some and in others the entire

anterior aspect of the soleus portions (Fig. 3). Some rotation invariably occurs. In order to record degree conveniently, the tendons are arranged in three groups. Group I includes cases of least rotation—in which no more than one third of the tendon posteriorly is contributed to by the soleus, and two thirds by the gastrocnemius. This group comprises 52 per cent of the 100 cases. Group II, including tendons whose rotation is such that approximately one half of the posterior surface is contributed to by each component, represents 35 per cent of the cases. Group III, in which rotation is extreme, so that two thirds of the posterior surface is made up of the soleus and only one third by the gastrocnemius, comprises 13 per cent of the cases. Rotation begins approximately 12 to 15 centimeters from the insertion, or about the level at which the soleus begins to contribute fibers to the tendon. Minimal rotation seems to be associated with lengthy fusion; since rotation occurs only in the "free" portion of the tendon, fusion of the gastrocnemius with a soleus muscle of extensive origin occasions an arrangement which allows the combined tendon to twist only in the distal half of the leg. Progressing slowly at first, the rotation can then become more marked in the lower 2 to 5 centimeters.

In a depression which crosses the posterior surface of the soleus muscle at about the junction of the medial and middle thirds, is lodged the slender plantaris tendon. It remains between the two components of the calcaneal tendon to a point 12 centimeters proximal to its insertion; having attained the medial aspect, it retains that relationship to its insertion (Figs. 1, a, 2, a and c).

When present, the plantaris tendon always occupies a position on the medial surface of the tendon, and varies only in its manner of insertion. In most instances the tendon of the plantaris is found to terminate in a fan-shaped aponeurotic expansion, related to the medial border of the distal extremity of the calcaneal tendon. This and other common arrangements may be conveniently described under the heading of types.

In specimens of type I, representing the commonest mode of insertion of the plantaris tendon (94 of 200 cases, or 47 per cent), the plantaris tendon inserts by a short fan-shaped expansion into the medial extremity of the superior tuberosity for insertion of the calcaneal tendon (Figs. 5, a and 2, a). In some instances the tendon also sends thin slips to the adjacent medial border of the calcaneal tendon. These slips, resembling fascial strands and not true aponeurotic extensions, are

readily removed from the tendon proper. In type II, second in the order of frequency (73 specimens, 36.5 per cent), the plantaris tendon inserts into the calcaneus, 0.5 to 2.5 centimeters anterior to the adjacent margin of the calcaneal

Fig. 4. Diagram to illustrate constitution of calcaneal tendon, showing form of each of its major divisions of gastrocnemius tendon and subjacent position of soleus tendon. Sites of usual incision (tendon, type II) are indicated.

tendon (Fig. 5, b); the long axis of the tendon is usually at an angle with, not parallel to, the long axis of the foot itself. The insertion supports the anterior wall of the bursa of the calcaneal tendon (Fig. 5, b, at cross). When large, the tendon frequently radiates in fan-shaped manner to the lacinate ligament and the fascia overlying the medial aspect of the calcaneus (Fig. 5, e); tendinous insertions are frequently quite expansive (Fig. 5, c), and often involve the fascial and ligamentous structures on the superior and medial surfaces of the foot. In type III (25 specimens, 12.5 per cent) the tendon is usually broad at the insertion; but, whether of large or medium size, it invests the dorsal and medial surfaces of the terminal portion of the adjacent calcaneal tendon (Figs. 1, a and 5, c). In specimens belonging to type IV (8 cases, 4 per cent) the plantaris tendon inserts chiefly into the medial border of the calcaneal tendon from 1 to 16 centimeters above the insertion of the latter into the calcaneus; occasionally, however, a lowermost slip may reach the bone (Fig. 5, d).

It is clear, then, that the plantaris tendon, in a preponderant percentage of cases, gains a virtually separate insertion into the os calcis. This it may do in any one of three principal ways: by implantation into the os calcis just in front of the calcaneal tendon, the long axis of the line of fixation being parasagittal; by insertion into the bone in such a way that the long axis is almost transverse, beginning, as in the former instance, at the medial margin of the calcaneal tendon; by attachment to the calcaneus medially, or to the calcaneal tendon posteromedially. In the first and second instances, the posterior border of the plantaris tendon is in contact distally with the anterior border of the calcaneal tendon; in the third instance, the lateral, or anterolateral surface is contiguous with the posteromedial surface of the calcaneal tendon. Even in those cases in which the insertion is into the calcaneal tendon, a few fibers may be sent downward for independent attachment to the os calcis.

In the 58 cases of absence of the plantaris in the present authors' series, there are 16 subjects in which agenesis is bilateral, and 26 specimens in which it is unilateral.⁴ Thus, in approximately one third of those persons in whom the muscle is wanting, it is bilaterally absent. The muscle is absent on the right side in 23 and on the left side in 35 of the 58 cases. Of the 26 specimens with unilateral absence, 19 are left, while only 7 are

⁴In a series of 881 extremities studied in the Anatomical Laboratory at Northwestern (see Daseler et al.), the plantaris muscle was wanting in 66 cases (7.6 per cent). In sets translated from the literature, the percentage absence is 7.05 (187 in 2650).

right. When the muscle and tendon are poorly developed on one side, they are usually equally weak on the opposite side.

B. Surgical Applications

The earliest orthopedic operation recorded is that of lengthening the Achilles tendon. It has become one of the commonest orthopedic procedures. Originally lengthening was accomplished by complete division, following which the gap was filled in by growth of the tendon. Many procedures were later devised. The usual procedure now is the open operation (Z-type tenoplastic) (see Fig. 4). Lengthening can also be accomplished by the subcutaneous method, but in carrying this out many difficulties have been encountered. Irrespective of what method was employed, in certain cases the portions of the divided tendons did not slide as readily as desired; whether the division was taken two thirds anteriorly and two thirds posteriorly, or two thirds medially and two thirds laterally, the results were similarly unsatisfactory.

In the usual open Z-type tenoplastic, the tendon is divided proximally in the medial half and distally in the lateral half, the incisions then connected by a longitudinal cut. After the proper amount of lengthening has been obtained, the tendons are sutured. This has the disadvantages, first, that scar tissue may render the tendon adherent to the skin and underlying structures, and second, that, with a complete division of the tendon, there is no way of controlling the amount of lengthening by "feel." This is important in cases of spastic paralysis since the object is to obtain a better muscle balance between the opposing groups, by weakening the stronger group. The amount of weakening to be obtained can best be judged if the lengthening is taken against the resistance of the tendon. With the subcutaneous method, and through sliding by of the fibers of the tendon (without a complete division), the introduction of sutures is not necessary and consequently there is less reaction. Additionally, the danger of infection is further reduced.

In the anatomical descriptions presented the authors show that in some cases the tendon fibers run practically straight and parallel (Fig. 2, a), while in others there is a complete rotation (Figs. 2, c and 3, c); all intermediate stages can be found, between these extremes (Fig. 1, a). In addition to difficulties occasioned by variation in the course of the fibers, others arise out of failure to divide the plantaris.

The objective of the surgeon is to divide one half of the fibers of the tendon of Achilles proxi-

mally and the other half distally, and at the same time divide the plantaris tendon with the simplest possible procedure.

Rotation of the calcaneal tendon was first brought to our attention by White,¹ who describes it as a constant occurrence which is established during embryological development. Because of this concept he advises sectioning the anterior two thirds of the tendon distally and the medial two thirds proximally. As demonstrated by the current observations, the rotation is variable, not constant. In carrying out White's method it is necessary in certain instances to make a third incision, dividing some gastrocnemius fibers laterally at the same level as the anterior section, in order to permit the severed fibers of the tendon to slide by. This is easily understood when it is remembered that a certain percentage of tendons of type I undergo very slight rotation (Figs. 2, a and 3, a). Therefore, enough of the gastrocnemius fibers remain undivided to require a third section before proper lengthening can be obtained. The method described by White is an excellent procedure in most cases, but unsuccessful in a sufficient number of those cases with slight rotation so that this study was thought advisable. In addition, the technique is difficult to perform subcutaneously, without visualization, because the distal end of the tendon lies deep, making the anterior half accessible only with difficulty. For this reason most surgeons expose the tendon with a longitudinal incision.

To overcome the difficulty just described the authors advise the following procedure. A proximal section is made to divide the posterior two thirds of the tendon (the gastrocnemius portion) (Fig. 6, b), and a distal one to separate the medial two thirds (the soleus fibers, including the plantaris tendon) (Fig. 6, c). In this way all of the fibers are severed either at the proximal or distal level, except in those cases in which there is virtually no rotation of the tendon. In such instances there are a few lateral fibers of the soleus left undivided at the level of the proximal incision. Since these fibers are mainly muscular, due to the extensive distalward site of origin (Fig. 2, c), they are readily torn (Fig. 6, d). As a consequence, the tendon is allowed to slide by, and desired lengthening is easily achieved.

The technique consists in a sterile preparation of the skin, and insertion of a thin tenotome (Fig. 7, a), scalpel-like, through the tendon so that two thirds of the tendon lies posterior to the tenotome. The tenotome is inserted so that the

Fig. 5, a to e. Types of tendinous insertion of plantaris muscle (adapted from Daseler and Anson, and augmented); specimen in Figure 5, b is of the left extremity, those in Figures 5, a and c to e are of the right. Bursa in 5, b is indicated by cross. Insert indicates areas of calcaneal insertion of plantaris tendon (types I, II and III) and of combined calcaneal and plantaris tendon (type IV), with areas of insertion numbered to record types. In insert tendon for type IV represented is an unusually long example. For tendon of type II, one of intermediate position is diagrammed; others would lie in front of or behind area indicated.

blade is parallel with the tendon. Next, the blade is turned so that it faces posteriorly, and the tendon is cut through toward the skin. Palpation by the thumb is used as a guide to the position of the

blade. The second incision is made distally by means of a curved tenotome (Fig. 7, b). The blade is inserted deep to the medial two thirds of the tendon. The tenotome is then drawn poster-

Fig. 6, a to d. Photographs (retouched) of surgical case, illustrating steps in procedure of tendon lengthening. iorly and medially to divide the medial two thirds of the tendon. The distance between the two divisions can vary from 1 inch to 4 or 5 inches, depending on the amount of lengthening required. The proximal incision should be made a

distance of 3 to 5 inches from the insertion of the tendon into the calcaneus, depending upon the amount of increase desired in the length of the tendon. The distal division of the tendon is always made at least one-half inch above the in-

Fig. 7, a and b. Photograph of tenotomes used. a, above. Used for proximal incision. Blade length 1.3 centimeters. b, Curved tenotome used for distal incision. Blade length 1.0 centimeters.

section of the Achilles tendon; in this way the tendon of the plantaris muscle is always included in the second incision. After the tendon has been divided in this manner, little force is required to lengthen the tendon, since the fibers will slide by quite readily. Judgment is required to establish the proper degree of lengthening. In cases of spastic paralysis the resistance present under anesthesia is a factor to be considered. The amount of correction can be measured by the amount of dorsiflexion taken. Palpation of the gaps in the tendon is also serviceable in establishing the degree of lengthening. Postoperatively the extremity is put in a cast to retain the new position and to allow the tendon to heal with retention of its increased length. A little less than the full correction obtained by surgery is to be maintained by the cast, in order to avoid undue strain and to prevent the formation of pressure sores.

In brief, then, the authors recommend the closed technique for lengthening the calcaneal tendon wherever its employment is possible. Basing a judgment upon an extensive anatomical study of cadavers and of postmortem specimens, and after considerable orthopedic experience, the authors feel justified in recommending their modified form of a well known surgical technique.

SUMMARY

In a group of one hundred lower extremities the constitution of the soleus and gastrocnemius tendons and of the combined calcaneal tendon was studied. Typical specimens are illustrated.

Some rotation of the gastrocnemius to the lateral side occurs in every case. The degree of rotation varies from slight (to render the soleus just visible in dorsal view), to extreme (causing the soleus component to be nearly obscured from the ventral surface). Cases of extreme rotation are far less common than those in which moderate rotation obtains.

Ability to separate the two components likewise varies from a condition in which it can be carried out with ease to one in which segregation is practically impossible. The width and length of the two components likewise vary to a marked degree.

The plantaris muscle and its tendon are subject to considerable variation in both origin and insertion. From an examination of 200 lower extremities, the authors set up four types of tendinous insertion. In a total of 810 consecutive lower extremities examined by the authors, the plantaris muscle is absent in 58 (7.16 per cent). In one third of the specimens in which the muscle is missing, the absence is bilateral.

Various types of transverse incisions were made on exposed tendons and ability to cause "slipping" by moderate dorsiflexion of the foot noted. From these observations, subsequently established clinically, it is concluded that if the posterior two thirds of the tendon be sectioned proximally and the medial two thirds distally, the desired degree of lengthening can be produced. It is also concluded that, by subcutaneous tenotomy rather than a more extensive tenoplasty procedure, it is possible for wholly satisfactory results to be obtained.

FOREIGN BODIES IN, AND IN RELATION TO, THE THORACIC BLOOD VESSELS AND HEART

I. Techniques for Approaching and Removing Foreign Bodies from the Chambers of the Heart

DWIGHT E. HARKEN, M.D., Lieutenant Colonel, M.C., A.U.S., Brookline, Massachusetts

THE purpose of this short discussion is to outline briefly a few aspects of the problem of foreign bodies in relation to the thoracic blood vessels and heart. Principal attention will be given: first, to the location of the missiles, second, to some reasons for the surgical removal of such bodies, and third, to the technique of approaching and removing fragments from the chambers of the heart. The necessity for brevity will dictate certain dogmatism and even the use of unsupported statements. Further clarification and support are to be presented (1, 2).

During the past 10 months with the thoracic unit of the 160th General Hospital 78 missiles were removed from within or in relation to the great vessels, at least 3 of which were embolic. During the same period 56 foreign bodies in, or in relation to, the heart have been removed, 13 of which were in the chambers of the heart. The great vessel series of 78 cases and the cardiac group of 56 cases, represent a total of 134 patients and 139 operations. There have been no deaths. A more precise breakdown in the distribution of these missiles is as follows: pericardial, 26; involving pericardium but principally pulmonary, 17; intracardiac, 13; on great vessels (and in walls), 35; intravascular (3 embolic), 7; on great vessels but principally pulmonary, 17; mediastinal but not directly on great vessels, 19, a total of 134, with no deaths.

The first diagram (Fig. 1) is a scale drawing of the heart and great vessels presenting the approximate size and location of a few of the foreign bodies first removed in the Unit. The gray shading represents a position impinging on the indicated structure, cross-hatching signifies an embolus and black indicates removal of foreign body from within the structure designated.

A current diagram (Fig. 2) has been prepared but in representing 129 missiles it has been neces-

sary to use point localization only. The same key to location is used in the margin, gray for foreign bodies impinging on the structure, cross-hatching for the embolic missiles and solid black for those lying within the structure outlined.

About all that such a gross method of localization conveys, is that the foreign bodies occupied a variety of positions, diffusely distributed about the mediastinum but that only one was found to lie in the left ventricle and none within the lumen of the thoracic aorta. It is, therefore, assumed that the direct entrance of foreign bodies of surgical size into either of these structures is rarely sur-

Fig. 1. A scale drawing of some of the first missiles removed in this clinic. Gray shading, impinging position; cross hatching, an embolus; black, within structure designated.

From the 160th General Hospital.

Fig. 2. Gross localization of foreign bodies presented in this discussion. Gray, impinging; cross hatching, embolic missiles; black within structure

vived. It is further suggested that fragments small enough to enter the left ventricle as migrating missiles are swept along by the high systemic pressure in contrast to those arriving at the right ventricle.

FOREIGN BODIES IN OR ON GREAT VESSELS

The danger of erosion and suppuration attending large retained missiles in relation to thoracic blood vessels is real. Three deaths from massive hemorrhage due to erosion have come to our attention. Furthermore, approximately 15 per cent of the thoracic vessel foreign bodies in our series have been associated with abscess formation, just

over 30 per cent were associated with other foreign material such as cloth or bone and 67 per cent showed pathogenic bacteria on culture. It is therefore, our policy to remove all foreign bodies measuring one or more centimeters in two dimensions, at times smaller missiles are taken out. The technical aspects of finding such fragments at operation are insignificant. We have failed in only one instance and that, the third case in this clinic. The fact that there have been no deaths supports our contention that removal is safer than retention.

In passing, attention is called to the three foreign bodies that have been established as embolic;

one was from the liver to the left pulmonary artery, another traveled from the heart to lodge in the innominate artery, and the third shifted from the left to the right pulmonary artery. All of these were removed without incident and with restoration of vascular continuity. These will be reported in detail separately (1).

FOREIGN BODIES IN OR ON THE HEART

Of the 56 foreign bodies in, or in relation to, the heart 13 have been removed from the chambers of the heart. The locations of the missiles in the chambers of the heart are indicated in the photograph (Fig. 3). Four were in the right auricle, 7 were in the right ventricle, 1 was in the left auricle and 1 was in a small cystic myocardial hernia of the left ventricle.

One fragment listed as within the right auricle lay in the interauricular septum and was associated with systemic embolus producing hemiplegia. Another fragment, described as in the right ventricle, was more evasive than the others (LeR.R. in Fig. 3). At the first operation with the patient in the dorsal decubitus position, the fragment wriggled from the grasping forceps and migrated to the right auricle just over the opening of the inferior vena cava. Three months later at the second cardiectomy the missile, though surgically exposed and visualized fell from the auricle into the right ventricle—the direction of fall being influenced by the patient's left lateral decubitus position. Finally at the patient's request a third cardiectomy was performed and the fragment was trapped in the apex of the right ventricle and successfully removed. The patient is now apparently in robust health. The last operation was recorded in colored moving pictures which demonstrate the firmly healed cardiectomy of the

Fig. 3. Photograph of intracardiac missiles that have been removed.

first operation and an area of damaged wall over the last intracardiac resting place of the migrating missile. This case demonstrates that even migrating foreign bodies can damage the overlying heart wall.

In spite of isolated reports of asymptomatic foreign bodies lodged in the heart, there is also evidence in the medical literature that some do cause death. These reports together with experimental evidence were the early basis for a policy of surgical intervention. It was found that foreign bodies placed inside the hearts of animals were associated with subsequent bacterial endocarditis. With such a background it was elected to remove 13 of 28 intracardiac foreign bodies. *It was felt that certain foreign bodies should be removed:* (1) to prevent embolus of the foreign body or the associated thrombus; (2) to reduce the incidence of

Fig. 4. Some of the incisions, indicating the variety of approaches used to obtain adequate direct exposure.

Fig. 5 Anteroposterior and lateral views of a foreign body in the chamber of the right ventricle. The right hemithorax was cleared of an infected hemothorax by decortication before these pictures were taken.

bacterial endocarditis; (3) to avoid recurrent pericardial effusions; and (4) to diminish the danger of myocardial damage with subsequent rupture or myocardial aneurysm.

It is now fair to say that this rationale originally borrowed from the medical literature and partially confirmed by personal animal experi-

mentation, has been clinically established. The evidence cannot be reviewed here, but will be further elaborated in a later publication (2).

Inevitably size and location are factors influencing surgical intervention. Small foreign bodies are probably less hazardous as they may be associated with less myocardial damage, they are

Fig. 6. Approach to right ventricle. Technique of removing the foreign body shown in Figure 5.

Fig. 7. A missile is shown to lie in the right auricle.

more readily and more firmly encapsulated and, finally, small foreign bodies are technically more difficult to remove. Accordingly in this clinic, the retention of 15 foreign bodies apparently in the heart has been regarded as less hazardous than their surgical removal. In short, Figure 3 illustrates the foreign bodies that we have elected to

remove. Size alone dictated removal of some of these, whereas, attending clinical manifestations influenced the decision to intervene in others.

Once the decision to remove a missile from the heart is made, the technical considerations are contingent upon surgical exposure and safe removal at cardiotomy.

Fig. 8. Sternal section provides better access to the right part of the right ventricle and the phrenic surface of the heart and pericardium. Sternal section can be carried out through an extension of the incision in Figure 6.

Fig. 9 The technique of approaching and exposing the fragment shown in Figure 7—anterior approach to the right auricle.

SALIENT FEATURES OF CARDIAC EXPOSURE

1. Adequate direct exposure of the involved region. This wide, direct exposure necessitates the use of a variety of approaches (Fig. 4) each one focused on the immediate problem at hand. This means that no standard or set cardiac approach is relied upon. The pleura is routinely opened.

2. Conservation of thoracic cage skeleton. The free division of ribs, cartilage, and the sternum is often essential; but complete reconstruction of an intact chest wall at end of operation must be borne in mind. Nothing is resected, nor discarded.

3. Minimal dislocation of the heart from its position of optimum function. Dislocation, manually or by means of an apical suture is badly tolerated and has caused runs of ventricular extrasystoles, diminished cardiac output, and transitory bundle branch block. Cardiac surgery with minimal dislocation of the heart, indeed, taxes the versatility of approach first emphasized.

4. Maintenance of a moist epicardium in the exposed heart. One per cent novocain solution has been used to keep the epicardium moist. It may have additional advantages.

Fig. 10. The approach used to remove a missile from the left auricle.

Fig. 11. A posterior approach to the heart is shown. The patient is in the ventral decubitus position.

Bearing in mind these principles of cardiac approach the left part of the right ventricle and the left border of the left ventricle have been exposed through the fifth or fourth intercostal space (Figs. 5 and 6). The pectoralis major muscle is split laterally and divided medially. The intercostal muscles are divided and the internal mammary vessels ligated. The suprajacent cartilage is divided near the sternum and the rib spreader inserted. Additional exposure can be obtained by the optional "T" incision and the division of the sixth and seventh costal cartilages (see Fig. 6). The pericardium and pleura are then opened freely. The foreign body can then be palpated if

it is in the right ventricle. Ordinarily we would not open a chamber of the heart to attempt removal of a missile not precisely located by palpation. Immediately over the foreign body a row of sutures is placed on either side of the projected incision. These are the hemostatic guy sutures or the control sutures by which the assistant prevents blood loss in the opened heart between intracardiac maneuvers. Actually we place two rows of control sutures on each side of the incision. The second row is a second line of defense as one of the first row is often pulled out. The missile is stabilized as well as possible with the fingers, a small epicardial incision is made with the

Fig. 12. A foreign body is shown in the interauricular septum and right auricle. The widened mediastinum was found, at operation, to be due to hematoma.

Fig. 13. An extracardiac approach to the right auricle used to remove the fragment shown in Figure 12. This avenue was necessary because the pericardial space was free and the auricular wall was too thin to hold guy sutures.

scalpel and a pointed forceps is thrust through the myocardial wall and spread to make an opening large enough to allow the insertion of a Kocher clamp. The foreign body is then grasped and extracted with the Kocher instrument. During these manipulations, the assistant affects hemostasis by crossing the control sutures. Once the foreign body has been removed, the inner rows of control sutures are tied across the incision. The second line of sutures are then tied over a free pericardial graft. Finally a larger free pericardial graft is placed over the first. No. 00 chromic catgut sutures on atraumatic noncutting needles are used. It is possible that silk would be preferable for use in closing the left ventricle. Postoperative cardiac tamponade is avoided by leaving the lateral angle of the pericardial incision open into the pleural space.

When the region to be approached is farther to the right or on the diaphragmatic surface of the heart, the intercostal incision is combined with transverse sternal section (Fig. 8). Mr. Tudor Edward's double retractor can be adapted for use in this procedure as illustrated. The sternum can be readily reconstituted with wire. When the auricle or the right side of the ventricle is to be approached, the reverse of this incision on the right side of the chest can be used in precisely the same way.

In approaching the right auricle ordinarily the right anterior approach is best, the third, fourth, or even fifth interspace being used, depending on the location of the foreign body. In the operation illustrated in Figures 7 and 9 the third interspace was used with section of the third and fourth costal cartilages near the sternum to gain exposure of the upper portion of the right auricle. In such approaches to the right auricle after the pericardium is opened, control sutures are placed in the auricular wall similar to those in the ventricle. As the auricular myocardium is often too thin to hold the sutures, the pericardium may be included with the auricle in the outer line, if there are existing adhesions as in this case.

A foreign body in the left auricle was approached as indicated in Figure 10. The fusion of the auricle to the pericardium made the intracardiac portion of this operation quite simple. The laceration of the auricle and pericardium was plugged by an infected clot. This patient had had three major and two minor hemorrhages.

A posterior approach exposing the left auricle either on the right or left side has been used to remove intrapericardial missiles but not for an intracardiac operation to date. The patient is placed in the ventral decubitus and the posterior incision provides exposure as illustrated in Figure

In one instance an extremely thin walled auricle was encountered in a completely free pericardial space. The auricle bled when an attempt to place the hemostatic sutures was made and this technique had to be abandoned. Similarly an approach through the auricular appendage was found unsafe. In this instance an extracardiac approach was devised by exposing the superior vena cava (Figs. 12 and 13) control tapes were placed around this vessel, an incision was made as illustrated and a forceps was slipped down the lumen into the auricle. By this maneuver the missile was removed without difficulty.

All of these approaches have been used successfully. Another extracardiac avenue to the heart by way of the pulmonary veins to the left auricle or even left ventricle has appealed to us but no occasion to use it has arisen.

Throughout these operations electrocardiograms have been taken, and these tracings are helpful in determining which manipulations are badly tolerated by the heart. Comments about these findings must be deferred.

Although the electrocardiogram may return to normal within a few hours, the patients who have had ventricular cardiomy are kept in bed for 3 weeks.

SUMMARY AND CONCLUSIONS

1. A series of 78 foreign bodies that have been removed from within, or in relation to, the

thoracic great vessels is discussed. Three of these were embolic.

2. A series of 56 foreign bodies that have been removed from within or on the heart is discussed. Thirteen of these were removed from the chambers of the heart.

3. Indications for the removal of certain great vessel and cardiac foreign bodies are discussed.

4. The salient features of cardiac exposure are presented.

5. Various techniques and approaches are outlined for removing foreign bodies from the chambers of the heart.

In conclusion it is again emphasized that the mortality and morbidity rates for retained foreign bodies in and in relation to thoracic blood vessels and the heart have not been completely assessed. However, in our series of 134 patients who have had foreign bodies removed, there have been no deaths and the men are clinically well. We hope that this experience supports our therapeutic policy.

FRACTURES OF THE UPPER END AND SHAFT OF THE HUMERUS

A Simple Conservative Method of Treatment

LAURENCE JONES, M.D., Beverly Hills, California

IN October 1942 (1) there was reported, in considerable detail, a reconstructive plastic operation made necessary by a previous resection of the head of the humerus. This operation was indicated when fracture dislocation of the head was present, or when severe comminution made satisfactory reduction impossible.

It was stated that this operation was reserved only for cases in which conservative measures had failed. In actual clinical experience the conservative treatment succeeded in at least 95 per cent of the total number of cases. This conservative method, previously undescribed, varies quite radically from other reported methods of treatment. It has been modified repeatedly over a period of 20 years. Because of a recent change of address, it is impossible at this time, to collect case reports of a rather large series of cases. However, the difficult nature of the illustrative case history should serve to demonstrate the efficacy of this method. It should also be apparent that the method would be applicable to other cases of simpler types. The comparative advantages of this treatment will be discussed briefly.

Mr. D. J. H., aged 66 years, slipped on the sidewalk falling directly on the point of the left shoulder. The arm and forearm were not extended. Immediately thereafter he noticed extreme pain in the left shoulder joint, aggravated by any movement. The patient was removed to the hospital and roentgenograms were made. These showed a badly comminuted fracture of the head, with overriding of the shaft (Fig. 1a). An abduction splint of special design (to be described in considerable detail) with incorporated

bracket for skin traction was applied. This bracket was designed to hold two lateral and parallel adhesive strapping bands. After 2 days there was little or no improvement in position. Realizing that skeletal traction was necessary a short Steinmann pin was drilled through the olecranon process of the ulna, and a yoke and different bracket were applied to the abduction splint (Fig. 2a and b). Through this device about 10 pounds of spring traction was applied. The angle of the brace was changed several times until the lower fragment was finally placed in satisfactory position with the upper comminuted fragments. All of this was checked by roentgenograms (Fig. 1 b, c, d). Within a week practically complete anatomical reduction had been obtained. Patient became ambulatory and was discharged home.

Two weeks after insertion, the Steinmann pin was removed. To prevent angulation and loss of position, the splint itself was not removed until firm bony union could be demonstrated by roentgenograms. This occurred approximately 3 months after date of initial injury. In the interim, patient received physical therapy consisting of electrotherapy and massage. No active or passive motion was permitted until firm bony union was demonstrated. Photographs taken 3 years after injury show that patient could carry 30 pounds of sand bags in full abduction (Fig. 3 a). A painless range of motion had been regained, patient's sole disability consisting of inability completely to extend injured arm overhead (Fig. 3 b, c, d).

The abduction splint (Fig. 4) which occupies such a prominent place in this discussion has been modified many times over a period of 20 years. It has become an indispensable addition to the armamentarium of conservative treatment of several conditions. Certain of its features are believed to be original, others were adapted from certain improvements found in other abduction splints. In clinical practice it is used for treatment of fractures of the clavicle. In addition, it has

Fig. 1 a, Photograph of roentgenogram illustrating fractures at, and above, the surgical neck with marked comminution of the head and overriding of the shaft. b, c, d

Photographs of serial roentgenograms illustrating gradual improvement in position following application of abduction splint.

Fig. 2. a, b, Photographs illustrating actual application of skeletal traction in recent patient having a fracture through the surgical neck of the humerus. These two views

show ambulant treatment and skeletal traction by Steinmann pin or Kirschner wire. Also improved bracket and yoke with details of spring traction regulated by wing-nut.

been found that immobilization of the shoulder promptly relieves severe pain which accompanies incomplete ruptures of the supraspinatus tendon. These are usually termed subacromial, or subdeltoid bursitis. Compared to other abduction splints it is very light, the frame weighing only slightly more than 2 pounds. This light weight is due to the fact that the frame is made of duralumin, or of thin sheet steel if this is not obtainable. All the various parts can be adjusted to the body contour by simple hand bending. Similarly, the angle of abduction can be adjusted. In treatment of fractures, the bracket in Figure 2a, b is added.

There is no need to describe in detail all of the features of the splint, such as the cock-up forearm splint, the elbow lock, the cupped-up arm rest, and the special design of the pelvic rest, as the accompanying photographs and illustrations do this adequately (Figs. 4a, 4b, 4c, 2a, and 2b). However, particular attention should be called to the key strap which starts at the upper bar posteriorly, and attaches to the lower bar anteriorly. This is always the first strap adjusted and has been called the "key strap." Adjustment of this strap assures a snug fit of the brace to the axilla. Also attention is called to the curve in the

Fig. 3. Photographs illustrating extent of functional return. a, Photograph illustrating patient carrying 30 pounds of sand bags in full abduction. b, Illustrating

complete return of external rotation. c, Illustrating complete return of internal rotation. d, Sole disability is inability to completely elevate arm to the overhead position.

Fig. 4. a, left and b, right. Anterior and posterior views of abduction splint with special built-in feature. The anterior view illustrates the two bands connected by a vertical connecting bar. When possible, the entire splint is made of duralumin. It weighs a little more than a pound completely equipped and is easily adjusted by simple hand bending. The upper arm band is curved upward anteriorly to avoid pressure on the female breast. The lower body band is designed to fit on the curve of the crest of the ilium. The forearm is curved upward anteriorly under the palm to give a "cock up" feature. The elbow lock, a, is adequately illustrated and capable of fixation or movement as desired. Special attention is called to the "key strap." This is the first strap adjusted and starts at the outer posterior end of the upper arm band and runs to the anterior surface of the lower arm band. The remaining straps pass circularly about the parts. (One central forearm strap is not shown in the illustration.) The frames can be used over and over again with only the felts and straps being changed. The splint can be reversed, for use on opposite side, by a brace shop.

anterior portion of the upper body band. This feature, now present in all the braces, is most valuable for the female patient. A band fashioned in this manner does not press upon the breast.

There has been little difficulty in getting the patients to wear this splint, even in cases other than fractures. Once fitted properly over an undergarment, the patient can then dress over it with a loose fitting dress, coat, or sport clothes, so that only the hand piece is visible; patients are pleased by this fact. This advantage does not apply while skeletal traction is necessary.

It has been our experience in fractures involving the upper two-thirds of the humerus, that lateral displacement of fragments is rarely a problem. Expressed in another manner, once the fragment is satisfactorily aligned in the anteroposterior roentgenogram, lateral views will show a satisfactory reduction in the great majority of cases.

Other methods of treatment for fractures of the upper end of the humerus and types of apparatus used are described in the various textbooks that concern fractures and dislocations. Many of these methods confine the patient to bed for the duration of the fracture; certain others, require the use of heavy plaster casts with incorporated devices for traction. Some, by their very nature,

prohibit the use of physical therapy during the treatment. As a result, circulation is impaired. This, in turn, often may result in delayed union and limitation of neighboring joint movements.

SUMMARY AND CONCLUSIONS

1. A simplified treatment of fractures of the upper two-thirds of the humerus is described.
2. The method has been used for a long period.
3. It has been found to be a satisfactory treatment for the great majority of fractures affecting this area. An illustrative case history is reported. Ordinarily this fracture would have required open reduction but it was treated conservatively with a good end-result. Approximately 90 per cent of fractures in this area can be treated by this simple ambulatory method.
4. An abduction splint that has been redesigned many times is described. In addition to the other uses, it has been found to be helpful in the conservative treatment of certain types of fractures of the clavicle, and in the relief of the pain that accompanies incomplete ruptures of the supraspinatus tendon (subdeltoid bursitis).

SURGERY AND THE CANCER PROBLEM

AN appeal is being made to the American public for sums aggregating several millions of dollars for a "fight against cancer." The cause is a worthy one, but distribution of money collected in its name entails considerable responsibility.

In general, cancer research has been interpreted to mean laboratory investigation with spontaneous and transplantable tumors, genetic studies, observations on the metabolism of cells *in vitro*, the chemistry of carcinogens, hormones, etc. Much basic information has been obtained concerning the nature of neoplasia; and such studies must be continued and expanded. However, unlike the situation in the fields of infectious and metabolic diseases where laboratory investigation has often afforded immediate benefit for clinical practice, cancer research has yielded comparatively little of direct benefit for the sufferer with cancer.

Great discoveries may come suddenly and from unexpected quarters; at the moment there is little indication that a biologic method for prevention and cure of cancer is imminent and there appears to be no one field that justifies intensive concentration of material resources and research effort at the expense of all other phases of the general problem.

Knowledge of cause does not assure means for control. It became possible to control the spread of small pox before the general acceptance of the germ theory of disease and long before the development of modern immunology. The specific cause of tuberculosis has been known for decades yet no specific therapy has been devised.

The endeavors of surgeons over the years to meet the challenge of cancer have resulted in appreciable advances in treatment. Six decades ago cancer of the breast was almost invariably fatal; today the patient with early cancer is offered at least a "60 per cent chance" for cure. At the turn of the century cancer of the stomach was regarded as hopeless. An interesting paper by no less an authority than the late William H. Welch, written in the eighties, four years after Billroth's first pylorotomy, included a discussion of why the surgical attack against cancer of the stomach was doomed to failure. Each one of the "insurmountable" obstacles mentioned has since been partially or completely surmounted. Today, the patient surviving five years following gastrectomy for cancer is no longer a medical curiosity. Fifteen years ago the patient with cancer of the lung, lower esophagus, proximal stomach, or pancreas was regarded as hopeless merely by

virtue of the location of the growth; today operations for removal of these neoplasms are carried out in many centers and patients have survived for years. Furthermore, improvement in cancer surgery based upon advances in supportive treatment permits appreciable extension of life in comfort for some patients belonging to a group previously regarded to be in the terminal stages of the disease. Indeed, prolonged survivals among them are increasing as time goes on. Irradiation therapy and radiobiology stem directly from an empirical clinical application of radium and x-rays to superficial neoplasms.

These endeavors must not be classified merely as phases in the routine care of patients by clinicians engaged in the routine practice of their profession. They constitute "cancer research" of a type, and no small measure of success has been attained.

The cause of cancer may be closely associated with the "cause" of living protoplasm itself and it is possible that sufficient fundamental knowledge of mechanisms of causation to enable control is still in the far future. Besides, as heretofore pointed out, knowledge of cause does not necessarily afford the means for control.

In the meantime the sufferer from cancer cannot await the future solution of the cancer problem. His situation is urgent and must be met immediately with the means at hand. With few exceptions, the only hope for cure lies with surgery, undertaken in the early stages of the disease; and for the exceptions, with irradiation, properly carried out. By continually improving the surgical and irradiation treatment progress will be made. If advances in the next 2 decades in the surgical management of cancer are comparable to those of the past 20 years, another important forward step will have been achieved which will be of direct benefit for the sufferers of this

disease. Appreciation of the proper place and importance of surgery in "the fight against cancer" is necessary in any plans for an extensive project along these lines. Failure of such appreciation would tend to restrain the further development of the one method of treatment with wide application that has been increasingly successful throughout the years and which along with irradiation in selected cases may continue to be the only generally effective therapy for a long time to come.

ALEXANDER BRUNSCHWIG.

A PLEA FOR THE PERSONAL CASE RECORD

ONE of the paradoxes of the day is the degree of ignorance concerning personal health and past illnesses found in the majority of individuals. A man who knows with certainty the exact status of a bank account, income tax, social security, insurance programs, et cetera, is conversely uninformed about the state of his present health and the true history of his previous illnesses. This deficiency is apparent on a review of the medical histories related by patients on successive hospital admissions or when the details are secured independently by two or more physicians. The errors in this information held by the patient are more obviously revealed by consulting the hospital records of past admissions. For example, the average patient does not know the operative findings, the nature of complications experienced, the proper final diagnosis, and the laboratory data of any surgical procedure performed on his person.

If one were to live in the same community from birth to death and always utilize the one community hospital and remain under the all-inclusive care of one doctor during this period, the present editorial and suggestions would be

unnecessary. In this age, however, almost every adult has consulted a number of physicians for various purposes, and each doctor is confronted with the problem not only of the chief or present complaint, but the condition of the patient as a whole and the relation of the present illness to past diseases or the handicaps of a body influenced by such past diseases. He may be content with a verbal report by the patient or he may deem it sufficiently important to consult the previous hospital records. In emergencies, there may be no opportunity to secure any information whatsoever.

The possession of a written, accurate personal health record or medical diary is as valuable as any birth certificate, wedding license, genealogical tree, diploma or any other treasured document. It can be achieved only by the meticulous accumulation of such information during one's lifetime.

Such a volume could start with the hereditary factors of familial diseases and list the causes of death of near relatives. From then, in orderly sequence could be related the type of birth and incidents in child development, such as ages at teething, walking and talking and the rate of growth. The diseases of infancy and childhood would be followed by those of adolescence, adulthood and senility in year by year notation. Each visit to a physician for minor illnesses would be recorded by the physician himself in a brief paragraph stating the diagnosis and treatment.

A separate sheet in the case record book would be used for noting the dates of vaccinations, tests for immunities, injections of sera and allergic reactions. A dental form

would be a corporate part of the system with the details of extractions, dental restorations and oral infections written by the dentist. All laboratory data such as urinalysis, blood counts, blood chemical studies, stool, sputum, blood typing, basal metabolic determinations would be listed on proper sheets with exact dates for future references.

In the case of females, the menstrual, gynecological, and obstetrical histories would be given in separate detail in the personal case record book. Pocket sheets for electrocardiographic tracings and miniature reproductions of roentgenograms would be integral parts of the record.

With each hospital admission the case record book is submitted by the patient and attached to the hospital chart until the day of discharge. An accurate summary of the past illnesses could be made by the interne without interrogating the patient. When patient left the hospital, a discharge note would include the exact diagnosis, the course of the disease, the complications, the surgical procedures and operative findings, if the treatment were surgical, the pathological diagnosis of any specimen removed and all laboratory and radiographic reports; this summary would be the responsibility of the attending physician.

Personal case records of the type described would be of great value to the patient and to the physician as well. They would have economic value because of the avoidance of so much unnecessary duplication of case recording. Such records would constitute an important source for statistical study if the method were commonly employed.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE author of *Plaster of Paris Technique*¹ believes that anyone with a moderate degree of manual dexterity can learn how to apply a plaster-of-Paris cast. He states correctly that the plaster cast is the best splint at the surgeon's command. It is inexpensive, durable, and is form fitting. It is a form of splint that renders itself to any specific situation.

Comparatively little has been written on the subject but the author calls especial attention to Luck's writings.

This book is written for students, house officers, and those who are called upon to treat injuries. The manuscript is well written. The illustrations are instructive. The book is divided into four sections: general considerations, the upper extremity, the lower extremity, and the vertebral column.

The author advises (1) no padding other than stockinette; (2) careful molding over bony prominences; (3) avoidance of wrinkles; (4) avoidance of adhesive beneath casts; (5) avoidance of any circular bandage other than sheet wadding under a cast; (6) application while bandage is sloppy wet; (7) no pulling during application.

He emphasizes the importance of pain, numbness, cyanosis, anesthesia, and edema as danger signals of complications. He believes it is unnecessary to split all casts immediately after application as a routine procedure.

The application of the full arm splint is well illustrated.

There are very few who would fail to enjoy and profit by reading this book. It should be in every plaster room and in every orthopedic library.

PHILIP LEWIN.

MANY new selections have been added to *The Classic Descriptions of Disease*² by Ralph H. Major which have definitely enhanced its value, though many a reader would doubtless wish to include still others depending on what his special interests are and who among the immortals are his favorites. One can derive much pleasure through reading the 287 selections from the original accounts of 195 authorities. These selections include a wealth of material of value to the practicing physician, teacher, and student.

The subjects chosen are divided into infectious diseases; diseases of metabolism; lead poisoning;

diseases of the circulatory, blood, kidney and respiratory systems; deficiency diseases; allergic diseases and diseases of the digestive tract.

In some of these chapters perhaps more is included than is necessary; in others, one could wish for more. Obviously there is no limit to the amount of material that could be included, and the author must be congratulated on the selections he has made. This volume deserves commendation and is a worthy addition to the physician's library.

THEODORE R. VAN DELLEN.

THE medical profession is provided with an excellent coverage of world's literature in the field of radiology by offering in *The 1945 Year Book of Radiology*³ concise but lucid abstracts of selected articles with adequate illustrations. In this the 50th anniversary year of the discovery of x-ray by Roentgen, with the world in turmoil, when the needs of the armed forces depleted the number of physicians in civilian practice to a bare minimum, it is gratifying to note the excellence and number of contributions published in the past year.

A perusal of this volume will acquaint the reader with the progress and latest achievements in diagnostic roentgenology and radiation therapy. It should stimulate him to refer to original articles for more detailed discussions. In collecting this material, the editors have selected 314 contributions from 91 clinical scientific publications of the United States and 16 other countries. The volume of 464 pages with 342 illustrations is well bound, and printed and comprehensively indexed.

Radiologists will not fail to add this volume to their library and look forward from year to year for its publication. To those physicians not familiar with the excellent content of the book, it is recommended without reservation.

EARL E. BARTH.

THE manual entitled *Roentgen Diagnosis of Diseases of the Gastrointestinal Tract*⁴ is the outgrowth of mimeographed outlines which the author John T. Farrell, used for some years in teaching students in radiology in the Graduate School of Medicine of the University of Pennsylvania.

The text is presented according to the "Standard Classified Nomenclature of Disease" published by the American Medical Association. Each pathologi-

¹PLASTER OF PARIS TECHNIQUE; IN THE TREATMENT OF FRACTURES AND OTHER INJURIES. By T. B. Quigley. New York, The Macmillan Co., 1945.

³THE 1945 YEAR BOOK OF RADIOLOGY. Edited by Charles A. Waters, M.D., and Whitmer H. Farrow, M.D. THEOPHILUS. Edited by Ira L. Kaplan, B.Sc., and M.D., Chicago: The Year Book Publishers, Inc., 1945.

⁴ROENTGEN DIAGNOSIS OF DISEASES OF THE GASTROINTESTINAL TRACT. By John T. Farrell, Jr., M.D. Springfield, Illinois: Charles C. Thomas, 1946.

cal condition is described in terms of alterations in contour, motility, and position.

The topics discussed include: esophagus; stomach; small intestine; colon; appendix; rectum; anus; combined diseases of the stomach and intestine and diseases of the intestine.

The methods of examination are presented at the beginning of each topic. A summary at the conclusion of each chapter classifies the diseases according to their effect upon contour, motility, and position.

This book is recommended as an excellent guide in the examination and diagnosis of diseases of the gastrointestinal tract.

R. B. LEWIS.

IN the small monograph, *Renal Tuberculosis and Roentgenologic Examination*,¹ Steinhert presents a survey and a discussion of the different diagnostic methods employed in the examination of 60 cases of surgical renal tuberculosis with special reference to the roentgenologic diagnosis. The material consists of the cases of patients with renal tuberculosis who were admitted into the Ullevål Hospital from 1938-1941. The value of excretory urography and the dangers which may attend instrumentation are discussed. An interesting and informative chapter is devoted to a discussion of renal reflux or back flow. The author advocates the application of pressure for adequate visualization of urinary tract by the excretory method. Short case histories of the 60 patients studied are found at the end of the volume. The literature, both European and American, is well covered. The illustrations are in the negative phase and depict all stages of renal tuberculosis.

The monograph—an instructive monograph deserving recommendation to urologists and roentgenologists as a valuable addition to their libraries—is translated into English with the summary translated into both French and German.

EARL E. BARTIL.

IN the monograph, *Cerebral Angiography with Perabrodil*,² Engeset has compiled the material from 1940 to 1944 at the Neurological Department of the University Clinic of Oslo. Since thorotrast was not accepted as being absolutely harmless, 35 per cent perabrodil has been used satisfactorily as the contrast substance since 1938. Thorotrast is used only when perabrodil produces pain and for patients with mental disorders. From 6 to 20 cubic centimeters per injection and from 6 to 52 cubic centimeters per seance are used. The material covers the author's experience in performing angiographies on 100 patients with a total of 190 injections. Patients with mental disorders often react violently so thorotrast is used instead of perabrodil. Death occurred in two instances. One patient in coma was

¹RENAL TUBERCULOSIS AND ROENTGENOLOGIC EXAMINATION. A SURVEY AND A COMPARISON BETWEEN THE EFFICIENCY OF THE DIFFERENT DIAGNOSTIC METHODS IN SIXTY CASES OF SURGICAL RENAL TUBERCULOSIS. WITH A SPECIAL VIEW TO THE ROENTGENOLOGIC DIAGNOSTIC. By RARET STEINHERT. Oslo: Grøndahl-Tryck, 1943.

²CEREBRAL ANGIOGRAPHY WITH PERABRODIL (CAROTID ANGIOGRAPHY). By ARNE ENGESET. Oslo: Fabritius & Sønners Boktrykkeri, 1944.

subjected to both ventriculography and angiography and expired a few hours later. The other patient, suffering from malignancy of the kidney with intracranial metastases, was subjected to angiography in the final stage of the illness. In neither instance was the cause of death ascribed to the injection of perabrodil.

In discussing the subject the author devotes sections to a historical review, to a comparison of contrast substances, to indications, contraindications, and technique; to the anatomy of the blood vessels, tumor localization, type diagnosis; to cerebral angiomas, cerebral aneurysms, cerebral arteriosclerosis and carotid thrombosis, and to therapy. The injections were all made by the neurosurgeon, Torkildsen, or his assistants. Brief case histories including a description of x-ray findings and excellent illustrations in the negative phase are used in presenting the clinical material.

The presence of several corrections is not found to be confusing. The volume is recommended to neurosurgeons, radiologists, and physicians interested in this specialized procedure.

EARL E. BARTIL.

IN this excellent monograph, *The Radiosensitivity of the Bone Marrow*,³ Denstad discusses a subject of much interest and vital importance not only to the radiologist but to all physicians who recommend the use of irradiation in the treatment of malignant and benign lesions. The work of previous investigators is adequately evaluated. The author has investigated both the indirect and the direct effect of irradiation.

The majority of the patients studied were undergoing radium and roentgen treatment for malignant tumors and lymphogranulomatosis at the Norwegian Radium Hospital. The methods of irradiation and hematological technique are discussed. The author concludes that irradiation does not generally produce any changes in the nonirradiated bone marrow. If the irradiation produces granulocytopenia, however, a minor degree of maturation inhibition is found within the myelopoiesis which is regarded as the cause of granulocytopenia, since fewer neutrophilic granulocytes capable of migration are found in the bone marrow. The anaphylactic or toxic factor probably has an inhibitory effect on the myelopoiesis stimulating the erythropoiesis. The indirect irradiation effect may possibly occur more easily in patients who are debilitated or whose erythropoietic mechanism is impaired prior to treatment.

In investigating the direct effect of irradiation on bone marrow, the author found the parenchymatous cells to be very sensitive. Doses of 100 r produced slight transient changes. The erythroblasts are somewhat more sensitive than the myeloid cells and the megakaryocytes. The youngest cell forms disappear early followed by the older forms when the dosage is increased. Early inhibition of karyokinesis was noted. Complete aplasia occurs after doses of

³THE RADIOSENSITIVITY OF THE BONE MARROW. By TORMEN DENSTAD. Oslo: Centralitykkeri, 1943.

2000 to 3000 r. Regeneration occurs early after small doses but later and more incompletely after larger doses. Complete regeneration has been observed after doses of 2000 to 3000 r. Only after larger doses of 3000 r or more is regeneration less complete, particularly the quantity of cells. Complete aplasia was found $3\frac{1}{2}$ years after the administration of 12,000 r. Erythroblasts regenerate first followed somewhat later by the myeloid cells. No difference in the effect of large doses of radium and x-ray was found. Irradiation produces inhibition of mitosis, a forced pathological maturation of the erythroblasts and disturbances of maturation within the myelopoiesis, all of which persist far into the period of regeneration.

This excellent monograph dealing with a subject of vital importance to any physician attending patients receiving either x-ray or roentgen therapy is highly recommended.

EARL E. BARTIS.

THE third edition of *Gynecologic Nursing* by Crossen and Hoffer has been written to fit in with the type of texts advised by the National League of Nursing Education. Its purpose is twofold: first, to teach the principles of gynecology to nurses so they may intelligently carry out various methods of examination and treatment and, second, to teach them gynecologic nursing methods.

This book of 256 pages is replete with 104 illustrations, glossary, index, and list of reference works. The authors believe that if nurses are well grounded in the theories and principles of gynecology, they may better understand the significance of diseases of the reproductive system as they pertain both to the individual and the community.

The book is divided into two parts; the first covering anatomy, physiology, disease and treatment; the second, outlining the nursing care of the gynecologic patient. Anatomy and physiology are dealt with in a simple, concise manner, terms are defined, and often lay terms are used to clarify the text. A wealth of illustrations placed close to the subjects under discussion make for easy reference. Important names and subjects are highlighted in heavy print for easy reference to the glossary where pronunciation and definitions are given. Review questions are given at the end of each chapter.

Symptoms and their significance, history, and examination are explained from the nurses' point of view, and the names and definitions of the many types of examination and their uses in differentiating gynecologic diseases are given. The entire field of gynecology is covered in the first two-thirds of the book, the latter third being reserved for the more strictly technical nursing care of the patient. Rather detailed operative procedures are fully discussed and explained. A healthy crusading spirit is noted throughout the text for the periodic examination and early treatment of pelvic disorders.

Under the nursing care section, detailed instructions discussing nursing care are given both regarding equipment and instruments needed as well as their use during the various gynecologic procedures. Many well placed illustrations admirably clarify the text, particularly in the discussion of subjects difficult to describe.

The sociologic, public health, and industrial problems are carefully covered. This volume is an excellent adjunct to nursing education.

BYROND HICKETT.

THE book entitled *Synopsis of Gynecology* by Crossen and Crossen is based on the 9th edition of the textbook *Diseases of Women* by the same authors. These authors believe that a synopsis is particularly valuable to students who intend to do general practice and to those intending to go into specialties other than gynecology because of the mass of material they must absorb from all other fields and because it offers a well digested, time saving method of becoming acquainted with gynecological disorders. Students specializing in gynecology will have a standard text on the subject, and the synopsis will offer them a small pocket review which can be read at odd moments.

This little volume, although in small print and very concise, frequently outline in form, is nevertheless quite detailed in many respects, often giving the background and early research involved in various subjects. With some 132 illustrations and 3 color plates well placed to aid in clarifying the text, there is a wealth of material crowded into this half inch thick volume. It is written with the student viewpoint in mind.

The early chapters cover anatomy and physiology of the pelvic organs including their endocrine functions, giving the background as well as modern concepts. Examination methods, both physical and laboratory, are well covered with descriptive illustrations liberally interspersed with the text. Diagnosis is thoroughly reviewed, with the signs and symptoms and their significance in localizing particular disease entities. Under treatment a note of caution is stressed in the indiscriminate use of the endocrines. Two full chapters deal with the external and lower genital tract including such subjects as relaxations and fistulas.

Several chapters are devoted to a discussion of the uterus, and they also cover inflammations, displacements, malignant and nonmalignant tumors. Pelvic inflammatory diseases are dealt with in two separate chapters outlining etiology, pathology, diagnosis, and treatment. There is one full chapter devoted to diseases of the ovary which include cysts and tumors. Menstrual disturbances are thoroughly gone into, and methods of investigation and treatment in relation to the various age groups are given. Sterility, sterilization, contraception and

premarital examinations are explained in considerable detail. Two chapters deal with miscellaneous subjects such as menopause, allergic disturbances, leucorrhea and the relationship of other body organs to the sexual organs.

Operative gynecology is covered in detail, both abdominal and vaginal, giving indications, dangers, preoperative and postoperative care. A final chapter deals with medicolegal problems.

The specialty of gynecology is thoroughly reviewed in this book. The authors state they do not include obstetrical problems, although one believes some space should be devoted to the cause and treatment of abortions and the early complications of pregnancy because in most hospitals these patients are cared for on the gynecological service.

BYFORD HESKETT.

THE author of *Biological Actions of Sex Hormones*,¹ Harold Burrows, is a well known experimental investigator who has written extensively on the nature and effects of the sex hormones. This book was written because the author believed, "that a coordinated summary of experimental inquiries in this field might be useful."

The book is divided into six sections. Part one is concerned with the gonadotrophins or the gonad stimulating hormones. Strictly speaking, gonadotrophins are not sex hormones but their inclusion in this book seems more than justified. The function of the gonads and their production of sex hormones is dependent upon and in turn has an effect upon the gonadotrophins. Part two has to do with a general consideration of the gonadal hormones: estrogens, androgens, and progestins; comparing and contrasting their chemical structure and the nature of their effects.

Part three deals more specifically with androgens, part four with estrogens and part five with progestins. The final section is entitled "The Sex Hormones of the Adrenal Cortex" and deals with the adrenal-gonad relationships. Adrenal "virilism and feminism" are also discussed.

There is a very complete index, both as to subject and authorities quoted. The latter serves as well for a bibliography, a method of presentation which has always seemed more sensible to the reviewer than having separate bibliographies at the end of each chapter or section of a book.

Burrows' review of the literature on each subject is exhaustive and in most portions the data is reviewed in a critical manner and the significance of the experimental work is evaluated. Only rarely does he compile the data on a subject with no attempt to evaluate its significance. One suspects these latter subjects are those with which he is less familiar or those which have been of no particular interest to him.

The book is well organized and well written but it probably will be of interest or of value to a very

limited audience. The data considered are almost exclusively those obtained from laboratory animals. On most subjects little or no clinical data are included. Inferences and conclusions drawn are physiological and rarely have clinical application. On the other hand the book will be of extreme value to the laboratory worker and to the rare gynecologist or endocrinologist who attempts to keep himself informed of the basic knowledge in his particular profession.

RONALD GREENE.

THE literature of hypertension and hypertensive disease has become voluminous and its evaluation difficult for the average physician. Herndon's slim book *An Introduction to Essential Hypertension*² provides an excellent introduction to the subject and should facilitate critical appraisal of current and future contributions in this field. Important and recent work is reviewed and included in an extensive bibliography. The author's conclusions are conservative. Essential hypertension is viewed as a deep-seated constitutional disorder affecting the whole vascular system. The etiology still appears to be unknown, and diagnosis is reached by the exclusion of other conditions. Modern study of the disease requires the skills of an internist, ophthalmologist, urologist, pathologist, and surgeon. Present treatment is merely palliative, and the disappointing results of medical care have stimulated a surgical attack of the problem. The effect of lowering the blood pressure is obviously beneficial. The most satisfactory surgical procedure, at present, seems to be bilateral section of the splanchnic nerves with lower dorsal and upper lumbar sympathetic ganglionectomy. Although an operation of this kind fails to remove the cause or alter the fundamental disturbance, it is believed worth while in certain carefully selected cases. The need and value of the patient's learning to live with a chronic condition is stressed. The author defines clearly and concisely the present status of our knowledge of an important and complex problem.

WALTER H. NADLER.

THE author of *Digitalis and Other Cardiotonic Drugs*,³ Eli Movitt, presents a useful manual.

Although the literature on digitalis has been extensive, it has embraced a host of conflicting findings and opinions, and no attempt has been made since the appearance in 1936 of Luten's treatise, to compile the sounder elements of clinical and laboratory research under separate cover. The book is organized under eight headings: (1) digitalis folium; (2), digitalis lanata; (3), lanatoside C; (4), other cardiotonic glycosides from digitalis plants; (5), strophanthus; (6), squill; (7), other cardiotonic agents of plant origin; and (8), cardiotonic glycosides of animal origin and a cardiotonic alkaloid. Each section contains a readable and orderly account of

¹AN INTRODUCTION TO ESSENTIAL HYPERTENSION. By Richard F. Herndon, M.D., F.A.C.P. Springfield, Illinois: Charles C Thomas, 1946.

²DIGITALIS AND OTHER CARDIOTONIC DRUGS. By Eli Rodin Movitt, M.D. New York: Oxford University Press, 1946.

³BIOLOGICAL ACTIONS OF SEX HORMONES. By Harold Burrows, C.B.E., Ph.D., F.R.C.S. Cambridge: At the University Press, 1945.

chemical structure, pharmacology and clinical application. Opinions and impressions of authoritative origin have been included with reasonable completeness and discretion on contested aspects of the subject. A few glaring errors in proofreading mar a serviceable and timely book.

EDITH B. FARNSWORTH.

IN the excellent book, *The Chemistry of Anesthesia* by Adrian¹ the author reviews the fundamental science, chemistry, and presents its significant relationship to anesthesia in an interesting and comprehensible manner.

In part I the author discusses inorganic chemistry as it applies to anesthesia. Special emphasis is placed on the chemical absorption of carbon dioxide in rebreathing appliances. The two types of mechanisms, the to-and-fro and the circle, are illustrated with simple explicit diagrams. Many practical aspects are included, such as, the temperature change during absorption of carbon dioxide, the resistance to movement of gases, and the clinical efficiency of soda lime.

Part II is devoted to the chemistry of the depressant drugs in common use for clinical anesthesia. The hydrocarbons as a group produce general anesthesia but variations in structure within this group alter potency, toxicity, or may even entirely remove physiological activity of the compound. There is a wealth of detail concerning the methods of preparation, properties, impurities, and chemical tests for ethylene and cyclopropane.

In the chapter on the alcohols one finds the basic information on changing narcotic potency, water solubility, and volatility by altering the structural formula. The chapter on ethers includes a chart showing the use of ethyl ether as the basic raw material in the manufacture of anesthetic drugs, and the wide distribution of the ethyl radical in the commonly used anesthetics. The importance of the purity of ether is stressed and tests for noxious agents and contaminants are described.

Halogenated compounds and the chemical and physical changes which occur by halogenation are discussed in detail. In the chapter on local anesthetic drugs there is a valuable table which included 20 different preparations comparing them as to chemical nature, solubility, and properties. Similar attention is given to the drugs affecting the autonomic nervous system and to the analeptics. The subject of explosions—factors influencing their production and the limits of inflammability—is treated briefly.

Part III deals with the biochemical aspects of anesthesia, i.e. the chemical changes in tissues induced by the administration of anesthetic drugs to man and animals. Animal experiments are wisely mentioned only when those on men are not available. Most theories of narcosis are based upon chemical, physical, or physicochemical phenomena observed

in cells. Each theory of narcosis is interrelated, and for this reason the entire subject is complicated. The author suggests that we may now have a few links to the still incomplete chain explaining the depression of the central nervous system. Then follows a description of the three separate compartments of body fluids—the vascular space, the interstitial fluid space, and the intracellular spaces—and the effects which anesthesia can have on the constituents of these fluids. There is also valuable information on the effects of anesthesia upon liver function, nervous tissue, and composition of urine.

Enzymes, vitamins, and hormones may play important rôles in anesthesia, and the data which exist at the present time are lucidly recorded. There is a thorough discussion of the detoxification and the elimination of anesthetic drugs.

The bibliography is especially fine in that it not only lists references according to the section of the book, but lists them according to each specific subject. It is a bibliography which can be used repeatedly. A glossary of terms, tables, and other information is also provided.

This book fills an important place in the library of the anesthesiologist. Heretofore it was necessary to search through many periodicals and books to find the material which is accumulated in this manuscript. Although it is basically for the anesthesiologist it has more than casual interest for the chemist, pharmacologist, and research worker. It is well written and well organized, and the subject becomes alive and comprehensible to the reader.

EDITH LASOV and MARY KARR.

IN its second edition, *Modern Anesthetic Practice* is a member of *The Practitioner Handbook* series has been completely revised. Like the first, it is planned for the occasional anesthetist, rather than the specialist. The contributors include the leading English anesthetists who have arranged a manual of basic principles which will be of value to the general practitioner to whom it is addressed. The specialist, however, will also find helpful suggestions.

The introduction warns that though the advantages accruing from the increasing complexities of anesthetic apparatus are obtained at a price; the simpler methods are safer for those not specially trained.

A brief outline of the essential physiology is included and the use of volatile agents, which is the chief reliance of the occasional anesthetist, is considered in some detail.

This reviewer feels that too much emphasis is placed on the use of nitrous oxide in major surgery and that the technique described, that of secondary saturation, introduces unjustifiable hazards of anoxia. In the hands of the occasional anesthetist, this technique may be even more dangerous than its use by the specialist.

MODERN ANESTHETIC PRACTICE. Edited by The Late Sir Humphry Rolleston, Bt. G.C.V.O., K.C.B., M.D., F.R.C.P., and Alan Moorhead, M.D., F.R.C.P., 2d ed. Published on behalf of *The Practitioner* by Eyre and Spottiswoode Ltd., 1946.

THE CHEMISTRY OF ANESTHESIA. By John Adrian, M.D. Springfield, Ill.: Charles C. Thomas, 1946.

The drugs and methods of administration of basal narcosis are described, including the administration of pentothal sodium rectally and intravenously. The discussion of endotracheal anesthesia is comprehensive.

In the chapter on spinal anesthesia it is recommended that the use of this method by the practitioner be confined to operations on the lower half of the body.

Considerable attention is given to the various phases of anesthesia and analgesia in obstetrics and it is stressed that spinal and caudal anesthesia for obstetric procedure should be reserved strictly for the specialist working under favorable conditions.

Premedication and methods of anesthesia for the child and for dental operations are discussed in detail.

Local anesthesia and refrigeration anesthesia are covered too sketchily for practical advantages. The anesthetic aspects of postoperative care are treated briefly, as are explosion hazards.

In general, the methods and apparatus described are applicable primarily to surgical practice in Great Britain and the American practitioner's interest will be largely academic.

MARY FRANCIS POE.

THE volume *Medicine in Industry*¹ by Bernhard Stern is one of the series published under the auspices of the Committee on Medicine and the Changing Order of the New York Academy of Medicine. The author is a lecturer in sociology at Columbia University and Visiting Professor of Sociology, Yale University. The book has been made available by the Commonwealth Fund.

The objectives of the Committee are defined as follows:

"To explore the possibilities and to formulate methods of maintaining and improving standards of quality in medical service, including medical research, medical education, the maintenance of health, both physical and mental, the prevention of disease, and the treatment of disease.

"To study the means of making available to larger groups of people and to the country as a whole the best known practice in preventive and curative medicine.

"To explore the possibilities and to formulate proposals of distributing these services not only to a larger number but also at a lower per capita cost than the present system permits."

The author traces in broad perspectives the social, economic, legal, and professional setting within which industrial medicine has matured and the development of the scientific knowledge which has given industrial physicians increased competence to cope with diseases affected by occupations. It delineates the prevailing disastrous rates of industrial disability and the limited extent of preventive services in industry. Recent developments in health and insurance programs are appraised and the

problems of the handicapped in industry outlined. The findings which emerge offer grave challenges to the public and to the profession, not merely to expand knowledge in the field of industrial medicine, but to apply more extensively the vast body of knowledge already available in the interests of the health and welfare of the nation.

The author has presented a somewhat sketchy but very thoughtful summation of the subject of industrial medicine. The general impression left by the book, is that both industrial management and the medical profession are not adequately coping with the problems presented in the field of industrial medicine and surgery.

C. T. OLSON.

PUBLISHED by the Commonwealth Fund, *Nursing in Commerce and Industry*² by Bethel J. McGrath is truly deserving of attention by the medical profession. Mrs. McGrath has done a most excellent job of presenting a picture of the modern nurse in commerce and industry. She is a dynamic writer and has gone into every phase of her subject with extreme thoughtfulness. Each chapter is followed by an extensive bibliography. So far as I know it is the only book published giving a comprehensive view of industrial nursing and medicine.

Although this volume has been written for the industrial nursing profession, it should be required reading for all medical students before graduation and for all physicians in any way connected with industry and commerce. It has been estimated that at the present time 90 per cent of the entire medical profession does not come in contact with industry and commerce, and except for the few who specialize in this field there is a definite lack of knowledge as to the importance of this field of medicine. This volume could very easily be used as a primer for the physician entering the field of industrial medicine.

The author, a registered nurse and a very exceptional personality, has written from the viewpoint of the nurse. One might almost conclude that industrial medicine came into being and has flowered solely through the efforts of the industrial nurse. Any contributions by the medical profession are considered of very recent origin. There may be a certain amount of casuistry on the part of the author. She states that the industrial nurse is not supposed to practice medicine, but details how the industrial nurse should set up a medical department and suggests that she be subject to the authority only of someone in the top management.

In her preface the author says: "The fact that the nursing profession, management, and medicine are not agreed as to her (industrial nurse) scope and function is not strange in so broad and diversified a field."

Because of a certain amount of confusion existing as to the placing of responsibility, the author takes a definite stand by suggesting throughout her book that the nurse can be more or less all sufficient in

¹MEDICINE IN INDUSTRY. By Bernhard J. Stern, Ph.D. New York: The Commonwealth Fund, 1946.

²NURSING IN COMMERCE AND INDUSTRY. By Bethel J. McGrath, R.N. New York: The Commonwealth Fund, 1945.

industrial work. There are many exceptional nurses in the industrial field and we would not argue but that some of them give far better service than do doctors. The fact that nurses are so prominent in the field of industrial medicine is due mainly to the fact that the medical profession has sadly neglected this field and that management, which is always looking for a bargain, is willing to utilize the services of a nurse in place of a medical man. American medicine is awakening to its responsibility and more and more is convincing management that all of its medical and health programs should be supervised by physicians. So far this idea has taken hold only in larger organizations, so that medical care in the majority of industries in the United States today is under the direction of nurses and part time doctors. I believe it will be definitely the attitude of the

American medical profession as time goes along that all industrial medicine should be directly under the supervision of the profession and that nurses in this field should be responsible not to someone in the top lay management but to a doctor, who in turn will report to the lay management.

There is a certain amount of danger in the attitudes created by this book in that nurses may be given the impression that they can take over tasks which legally and properly belong to the medical profession and that it is not required that they have direct medical supervision. As long as the medical profession does not bestir itself to take a more active interest in industrial medicine, Mrs. McGrath's teachings are justifiable. The responsibility for the present situation rests directly upon the medical profession.

C. T. Olson.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

W. EDWARD GALLIE, Toronto, *President*
IRVIN ABELL, Louisville, *President-Elect*

Committee on Arrangements
HOWARD A. PATTERSON, *Chairman*; FRANK GLENN, *Secretary*

PROGRAM FOR THE 1946 CLINICAL CONGRESS IN NEW YORK SEPTEMBER 9 TO 13, 1946

THE thirty-second annual Clinical Congress of the American College of Surgeons will be held in New York September 9 to 13 at the Waldorf-Astoria. Had war conditions not made voluntary cancellation of meetings since 1941 advisable, this would have been the thirty-sixth Congress. Practically five years will have elapsed since the Boston meeting, which will give the September Congress the significance of a quinquennial event. It is with due appreciation of this fact, and of the epochal advances in medical science achieved during the war years, that the program is being planned.

The Fellows of greater New York are working to facilitate the utilization of the clinical resources of that great medical center as background for the series of scientific sessions and hospital conferences which will be held in the headquarters hotel. Demonstrations, clinics, and clinical group conferences will be held on each of the 5 days in selected hospitals, to supplement the panel discussions, symposia, forums, and other scientific meetings at the Waldorf-Astoria in which leaders of the surgical profession from many sections of the country will take part. Visitors of outstanding reputation in the hospital field will join with local authorities in presenting a varied, timely, and stimulating program for hospital personnel.

SIXTH NEW YORK CONGRESS

This will be the sixth time that the Clinical Congress has been held in New York. The first time was in 1912, when the old Waldorf-Astoria was the scene of the third Congress. Dr. George E. Brewer was the Chairman and Dr. Charles H. Peck the Secretary of the 1912 Committee on

Arrangements. Dr. Edward Martin of Philadelphia was then President of the Clinical Congress of Surgeons of North America. More than 2,600 physicians registered, and the lack of organization for regulating the attendance at the clinics precipitated the proposal by Dr. Franklin H. Martin at the business meeting on Friday afternoon, November 15, for the creation of the college.

At the same meeting Dr. Allen B. Kanavel presented a resolution which provided that "some system of standardization of hospital equipment and hospital work should be developed, to the end that those institutions having the highest ideals may have proper recognition before the profession, and that those of inferior equipment and standards should be stimulated to raise the quality of their work. . . ." and that "the President of the Congress be authorized to appoint a committee from the profession, delegated to carry the spirit of this resolution into effect, and report at the Clinical Congress in 1913." This resolution was adopted.

Another significant event was the appointment, during an evening session given to the consideration of cancer, held in Brooklyn, of a committee that formed the nucleus of the American Society for the Control of Cancer which was organized following the Congress of Physicians and Surgeons of North America on May 22, 1913.

Thus the plans for formation of the College and for the inauguration of activities in two fields which have always been among its major concerns, hospital betterment and cancer control, were initiated at the 1912 Clinical Congress in New York, 5 years before the Congress was amalgamated with the American College of Surgeons. Later Congresses were held in New York in 1919, 1924, 1931, and 1938.

FIRST POSTWAR CONGRESS

The first postwar Clinical Congress will differ from the meetings for several years prior to the war in that a return will be made to the original custom of holding the Presidential Meeting on the opening evening, Monday, and the Convocation on the final evening, Friday, instead of combining them on the first night. There are several good reasons for the change among which is the likelihood of having several hundred surgeons, who have been received into fellowship *in absentia* during the years in which no Convocation was held, added to the number of initiates for the current year who will be present for the initiation ceremonies. Related to this is the need for relieving the pressure for hotel accommodations by distributing the attendance better throughout the week than would be possible if the Convocation were held on the opening night.

COMMITTEE ON ARRANGEMENTS

A representative Committee on Arrangements has been appointed consisting of the following members:

Howard A. Patterson,
Chairman
Frank Glenn,
Secretary
Frank E. Adair
Albert H. Aldridge
Thomas M. Brennan
E. Jefferson Browder
George F. Cahill
Henry W. Cave
Ralph Colp
Edward J. Donovan
Merrill N. Foote
John H. Garlock

Charles A. Gordon
George J. Heuer
J. William Hinton
George H. Humphreys
William F. MacFee
John H. Mulholland
W. Barclay Parsons
Otto C. Pickhardt
Thomas H. Russell
Raymond P. Sullivan
Howard C. Taylor, Jr.
William Crawford White
Philip D. Wilson

The Committee has been working diligently for several weeks on the meeting plans and the clinical program and there is every indication that this will be a most successful congress.

CLINICAL PROGRAM

The hospitals and medical schools of greater New York are co-operating in scheduling operative and nonoperative clinics, and group clinical conferences. Visiting surgeons will have ample opportunity to attend well arranged programs of many different kinds in several of the excellent hospitals in the area. General and special demonstrations will be held such as fractures, cancer, maternal morbidity, and end-result studies; clinicopathologic and x-ray conferences; newer diagnostic and therapeutic procedures; preoperative and postoperative supportive treatment; anesthesia; and reconditioning. The newer tech-

niques and surgical procedures may be observed by those who are interested in them.

The medical schools will hold a series of exhibits demonstrating their work which will be on display in their affiliated hospitals. The program of each hospital will be arranged to cover subjects in general surgery, obstetrics and gynecology, fractures, orthopedic surgery, thoracic surgery, neurosurgery, genitourinary surgery, ophthalmology, and otolaryngology.

PRESIDENTIAL MEETING

On Monday evening in the Grand Ballroom the Presidential Meeting will be opened with the impressive processional of the officers, regents, and honorary guests. Welcome to the assembly will be extended by the chairman of the Committee on Arrangements, Dr. Howard A. Patterson. Dr. W. Edward Gallie of Toronto, President of the College, will preside and will deliver the Presidential Address. An inaugural ceremony will be held for the incoming officers. Foreign guests will then be introduced.

A new feature to be included in the Presidential Meeting this year will be the first Martin Memorial Lecture. Dr. Edward D. Churchill of Boston has accepted the invitation to give this lecture. This lectureship was established upon motion of the Board of Regents at its midyear meeting on April 1, as a memorial to both Dr. Franklin H. Martin and Mrs. Martin. The founder of the College and of SURGERY, GYNECOLOGY AND OBSTETRICS was joined by his wife in making the College the beneficiary at their deaths of the Journal, together with its physical plant operated by the Surgical Publishing Company of Chicago, of which they were the owners. Doctor Martin died in 1935 and Mrs. Martin in 1945.

The Martin Memorial Lecture is to be given annually during the Clinical Congress. It will deal with a scientific subject of the author's own choosing, and it will supplant the former Annual Oration in Surgery.

CONVOCATION

It is planned this year, for various reasons, to depart from the custom of recent years of holding the Presidential Meeting and the Convocation on the same evening. The Convocation is therefore scheduled for Friday evening. An Assembly of Initiates will be held prior to the Convocation on Friday in order to instruct them in the Convocation procedure and other matters.

The Convocation will open with a processional of officers, regents, and governors. The President, Dr. Irvin Abell, will preside and will make the

opening remarks, confer the honorary fellowships, and present the candidates for fellowship. Following this ceremony, a speaker to be announced later will give the Fellowship Address.

SCIENTIFIC SESSIONS

Eminent surgeons and specialists, recognized as authorities in their fields, will address the scientific sessions, to be held on Tuesday, Wednesday, and Thursday evenings. These will be conducted as symposia, and the subjects for the three nights will be as follows: Tuesday, "Care of the Patient Before and After Operation"; Wednesday, "Venous Thrombosis and Prevention of Pulmonary Embolism"; and Thursday, "Antibiotic and Chemotherapeutic Agents in Surgery." The annual Fracture Oration will be included in the Wednesday evening program.

Single major panel discussions will be held every afternoon, from Monday through Thursday, as follows:

Monday, 1:30 to 3:00—Rehabilitation of the Surgical Patient and Early Ambulation

Monday, 3:30 to 5:00—The Treatment of Cancer of the Large Bowel

Tuesday, 1:30 to 3:00—Thiouracil in Thyroid Disease

Tuesday, 3:30 to 5:00—Recent Trends in the Management of Carcinoma of the Cervix

Wednesday, 1:30 to 3:00—Anesthesia

Wednesday, 3:30 to 5:00—Protein Metabolism in the Surgical Patient

Thursday, 1:30 to 3:00—Spinal Cord Injuries

Friday, 1:30 to 3:00—Surgery of the Stomach

Friday, 3:30 to 5:00—Surgery of the Vascular System

A symposium on fractures and other traumas will be held on Tuesday afternoon, and a symposium on cancer on Wednesday, from 2:00 to 4:00 o'clock.

Concurrent panel discussions are also planned for Friday afternoon. Subjects to be discussed are plastic surgery, thoracic surgery, urology, neurological surgery, orthopedics, and obstetrics.

OPHTHALMOLOGY AND OTORHINOLARYNGOLOGY SESSIONS

Ophthalmology panel discussions will be held Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock on, respectively, "Retinal Detachment," "Glaucoma," and "Keratoplasty." On Tuesday evening at 8:00 o'clock there will be a symposium on "Orbital Reconstruction Including Prosthesis." On Thursday evening a scientific session is planned with the following as the subjects: "Recent Advances in Ophthalmology";

"Medical Treatment of Glaucoma"; and "Visual Disturbances Associated with Head Injuries."

Otorhinolaryngology panel discussions will be held Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock on, respectively, "Treatment of Meniere's Disease," "Osteomyelitis of the Skull," and "Rehabilitation of War Deafness." On Tuesday evening at 8:00 o'clock there will be a symposium on "Treatment of Deafness" and on Thursday evening a symposium on "Surgery of the Nasal Accessory Sinuses."

Of interest to ophthalmologists, otorhinolaryngologists, and other surgeons will be a symposium to be held on Wednesday evening at 8:00 o'clock on "Plastic Surgery of the Head and Neck."

FORUMS ON FUNDAMENTAL SURGICAL PROBLEMS

The Forums on Fundamental Surgical Problems will be conducted on Tuesday, Wednesday, Thursday, and Friday mornings. Included in them will be brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties. No prepared discussions of the reports are planned, but questions and comments will be invited. Especially keen interest is expected in these sessions this year because of the accumulation of the results of 5 years of work since the last Clinical Congress. Dr. Owen H. Wangenstein of Minneapolis, chairman of the committee which is planning the program, is working toward representation of as many as possible of the various university departments of surgery in this presentation of clinical and experimental research work.

The enlistment of the interest of young men who are doing original work, through the forums, is one of the most beneficial results of these sessions which are now considered to be an indispensable feature of every Clinical Congress.

HOSPITAL CONFERENCE

Dr. W. Edward Gallie, President of the College, will address the opening session of the twenty-fifth annual Hospital Standardization Conference on Monday morning at 10:00 o'clock in the Grand Ballroom, and will preside at the meeting, which will be attended by surgeons and hospital representatives. Following Dr. Gallie's résumé of the Hospital Standardization program of the College, including plans for the future, there will be reports on the progress of the 1946 Hospital Standardization survey, final results of which, including the Approved Lists of hospitals, cancer clinics, and approved hospitals for graduate training in surgery, will be announced at the end

of the year, instead of at the Clinical Congress as was the practice in former years.

The remainder of the Monday morning session will be devoted to talks by medical and hospital authorities on advances in medicine and surgery as they affect the postwar hospital, with particular consideration of their relation to the Hospital Standardization program.

The afternoon conference on Monday will be concentrated upon current problems and the outlook for the future in nursing service. The Tuesday morning conference will have as its main subject personnel management, and the Tuesday afternoon session will be centered around personnel problems in specific fields, such as dietary, laboratory, medical records, medical social service, x-ray, physical and occupational therapy, and other professional and semi-professional services. The discussions will emphasize the importance of scientific management techniques in assuring high quality service from personnel.

The Wednesday morning conference will have as its main theme the importance of assuring high standards of care to the community and all patients through providing in the general hospital facilities for all types of illness. The subject will be discussed from the standpoint of psychiatric, tuberculous, cancer, chronically ill, and convalescent patients. The Wednesday afternoon conference will center mainly around discussion of ways of improving co-operation between general hospitals and special hospitals in the care of all types of special patients.

The Thursday morning conference will revolve around the physical plant of the hospital and the importance of improvement and modernization in raising standards of care of the patient. New mechanical and technical developments will be presented. The afternoon conference will be devoted to the hospital as the health center of the community, with consideration of the effects of this concept upon hospital public relations and upon the progress of preventive medicine and public health.

An evening conference will be held at 7:00 o'clock on Tuesday. This will be devoted to discussion of the responsibilities of trustees, and members of governing boards will be especially invited to attend and to participate. A conference will be held on Wednesday evening also. This will be a round table conference on responsibilities of hospital administrators, and the preparation which is necessary to enable them to cope successfully with the wide range of administrative problems. The discussion of these problems will interest all hospital personnel.

ANNUAL MEETING OF FELLOWS

The annual meeting of the Governors and Fellows will be held on Thursday afternoon at 1:45. There will be election of officers and governors. The annual meeting affords the Fellows of the College an opportunity to hear reports of officials on the work of the organization, and to learn how it has not only raised the professional and ethical standards of surgery, but has also promoted good hospitalization and general improvement in the practice of medicine in the United States and Canada. Each Fellow has a personal part in this work and may extend the influence of the College materially in his local community. Hospital Standardization alone offers him unlimited opportunity to provide better medical care for his patients in the hospital in which he works through continuous progress in applying the principles of the Minimum Standard which insure the best care of the patient.

Every Fellow will want to attend this important meeting, at which reports will be presented on financial affairs; Hospital Standardization; Graduate Training in Surgery; Medical Motion Pictures; Public Relations; Library and Literary Research; the work of the state and provincial credentials committees, committees on applicants, and the Committee on History Reviews; Sectional Meetings, 1946; and the Department of Clinical Research, including cancer clinics, medical service in industry, the Committee on Cancer, and the Committee on Fractures and other Traumas. Dr. Abell will report on administration of the College, staff changes, and retirements, and Dr. Arthur W. Allen, Vice-Chairman of the Board of Regents will discuss "Fellowships, Obligations and Opportunities."

STATE AND PROVINCIAL EXECUTIVE, CREDENTIALS AND JUDICIARY COMMITTEES

On Wednesday morning from 9:00 to 12:00 o'clock the State and Provincial Executive, Credentials, and Judiciary committees will meet to discuss their respective activities.

MEDICAL MOTION PICTURES

The latest available films showing surgical procedures and related subjects will be shown in the medical motion picture exhibits which will be held daily. These are a much appreciated feature of the Clinical Congress. Despite the decrease in production of such films during the war period, a surprising number of new pictures are being received by the College for review.

The schedule will be so arranged as not to conflict with either the clinical program at the

hospitals or the scientific sessions. Both sound and silent, standard and color films will be shown, all of which have been approved by the Committee on Medical Motion Pictures.

TECHNICAL AND SCIENTIFIC EXHIBITION

The technical exhibit, together with the registration and clinic ticket bureaus, will be located in the Basilidon Room, Jade Room, and Astor Gallery, all on the third floor of the hotel. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, pharmaceuticals, and publishers of medical books will be represented in the exhibition. The technical exhibits will demonstrate many of the newer features learned from our experience in the war.

ADVANCE REGISTRATION

The hospitals and medical schools of New York afford accommodations for a large number of visiting surgeons. However, in order to insure against overcrowding, attendance at the Congress will be limited to the number that can be comfortably accommodated at the meetings and also by accommodations in the hotels. It is therefore expected that surgeons who wish to attend the Congress will register in advance.

The members of the Board of Regents regret that conditions beyond their control will not permit unpaid registration at the 1946 Clinical Congress as had previously been indicated. At their midyear meeting on April 1, 1946, they voted to restore the registration fee of \$5.00 for Fellows and for endorsed Junior Candidates. Non-fellows attending as invited guests of the College will pay a fee of \$10.00. No fee will be required of initiates in the classes of 1942 through 1946.

To each surgeon who registers in advance a formal receipt will be issued. This is to be exchanged for a general admission card upon his registration at headquarters during the Congress. This card is not transferable and must be presented in order to obtain clinic tickets and admission to scientific sessions.

HOTEL RESERVATIONS

With the present congested hotel conditions, Fellows are urged to make early reservation at a hotel of their choice in the New York area. Should difficulty be experienced in obtaining accommodations, the College will upon request forward a special form "Application for Hotel Accommodations" which may be sent to the Housing Bureau of the American College of Sur-

geons, Room 1536, 233 Broadway, New York 7. The Committee on Arrangements feels that the housing situation will remain acute in New York for some time to come and in consequence recommends that all Fellows who can do so, make their own arrangements for lodgings while there. The New York Convention Bureau is co-operating by reserving as many hotel rooms as can be obtained for Clinical Congress registrants.

Following is a list of hotels:

	Minimum Rates with Bath	
	Single	Double
Allerton House, 143 East 39th Street	\$2.75	
Allerton House for Women, 130 East 57th Street	3.00	
Ambassador, Park Avenue & 51st Street	6.00	
Astor, Broadway & 44th Street	3.50	\$4.00
Barhizon (Women) Lexington Avenue & 63rd Street	3.50	
Barclay, 11 East 48th Street	6.00	8.00

Woodstock, 127 West 43rd Street	3.00	5.00

CLINICAL CONGRESS PROGRAM IN BRIEF

Monday, September 9

- 10:00 General Assembly for Surgeons and Hospital Representatives, Grand Ballroom
 1:30-3:00 Panel Discussion, Empire Room
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference, Sert Room
 1:00 Surgical Film Exhibition (General), Grand Ballroom
 3:00-5:00 Panel Discussion, Empire Room
 8:00 Presidential Meeting, Grand Ballroom

Tuesday, September 10

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 10:00 Hospital Conference, Sert Room
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Jensen Suite
 9:30-12:00 Forum on Fundamental Surgical Problems, Grand Ballroom
 10:00 Surgical Film Exhibition (General), Empire Room
 11:00 Panel Discussions
 Ophthalmology
 Otorhinolaryngology
 1:30-3:00 Panel Discussion, Grand Ballroom
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference, Sert Room
 2:00 Symposium on Fractures and Other Traumas
 2:00 Surgical Film Exhibition (General), Empire Room
 3:30-5:00 Panel Discussion, Grand Ballroom
 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 7:00 Hospital Conference—Trustees, Sert Room
 8:00 Scientific Session, General Surgery, Grand Ballroom
 8:00 Scientific Session, Panel Discussion Ophthalmology, Jensen Suite
 8:00 Scientific Session, Otorhinolaryngology, Le Perroquet Suite

Wednesday, September 11

- 8:00 Meeting of Cancer Committee, Carpenter Foyer and Dining Room
 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected Local Hospitals
 9:30 Hospital Conference, Sert Room
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 9:30-12:00 Forum on Fundamental Surgical Problems, Grand Ballroom
 10:00 Surgical Film Exhibition (General)
 State and Provincial Committees:
 Judiciary Committees
 Executive Committees
 Credentials Committees and Committees on Applicants
 11:00 Panel Discussions
 Ophthalmology
 Otorhinolaryngology
 12:00 Meeting of Board of Governors, Jensen Suite
 1:30-3:00 Panel Discussion, Grand Ballroom
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals

Empire Room

- 2:00 Symposium on Cancer, Empire Room
 2:00 Surgical Film Exhibition (General)
 2:30 Hospital Conference, Sert Room
 3:30-5:00 Panel Discussion, Grand Ballroom
 6:00 Vandyck Reunion Dinner, Le Perroquet Suite
 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 7:30 Hospital Conference, Sert Room
 8:00 Scientific Session, General Surgery, Grand Ballroom
 8:00 Scientific Session (Eye, Ear, Nose and Throat), Empire Room

Thursday, September 12

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 9:30 Hospital Conference, Sert Room
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 9:30-12:00 Forum on Fundamental Surgical Problems, Grand Ballroom
 10:00 Surgical Film Exhibition (General), Empire Room
 11:00 Panel Discussions
 Ophthalmology
 Otorhinolaryngology
 1:30 Adjourned Meeting, Governors, Grand Ballroom
 1:45 Annual Meeting, Fellows, Grand Ballroom
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference, Sert Room
 3:00 Panel Discussion—Graduate Training in Surgery, Jensen Suite
 3:30-5:00 Panel Discussion, Grand Ballroom
 3:30 Surgical Film Exhibition (General), Empire Room
 3:30 National and Regional Fracture Committees, Le Perroquet Suite
 4:00 Committee on the Library, Room 4-J
 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 8:00 Scientific Session, General Surgery, Grand Ballroom
 8:00 Scientific Session, Ophthalmology, Empire Room
 8:00 Scientific Session, Otorhinolaryngology, Sert Room

Friday, September 13

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 9:30-12:00 Forum on Fundamental Surgical Problems, Grand Ballroom
 10:00 Surgical Film Exhibition (General), Empire Room
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00-4:00 Panel Discussions
 Obstetrics, Sert Room
 Plastic Surgery, 4-U Blue Room
 Neurological Surgery, Assembly Room M-N
 Thoracic Surgery, Jensen Suite
 Urology, Le Perroquet Suite
 Orthopedic Surgery, Carpenter Foyer and Dining Room
 2:00 Surgical Film Exhibition (General), Empire Room
 8:00 Convocation, Grand Ballroom

COLLECTIVE REVIEW

A SUMMARY OF THE SURGICAL ASPECTS OF CERTAIN SULFONAMIDES AND ANTIBIOTIC AGENTS

JOHN HENDERSON, M.D., New York, New York

WITH the report of Domagk in 1935 that a certain dye would protect mice against lethal doses of streptococci, and the subsequent proof by Trefouel and others (7, 11, 27, 68) that this effect was due to hydrolysis of the dye within the body to sulfanilamide, an era of chemotherapeutic development was initiated which has been startling in the complexity and variety of chemotherapeutic agents which have become available within a short span of years. Of the many classes of compounds which have become of major therapeutic importance, the sulfonamides and that group of antibacterial and antifungal substances derived from living sources, known as the antibiotics, are especially important in surgical therapy.

The chemical structure of the sulfonamides is essentially simple and is based fundamentally upon the benzene ring. When an amino ($-NH_2$) group is substituted for one of the hydrogen atoms of this ring, aniline is formed; the substitution of a sulfonyl group ($-SO_2OH$) for another hydrogen of the benzene ring produces sulfanilic acid. If the ($-OH$) group then is replaced by an amino ($-NH_2$) group, the resulting compound is para-aminobenzenesulfonamide, or sulfanilamide.

With sulfanilamide as a starting point, one of the hydrogen atoms of the ($-SO_2NH_2$) group may

be replaced by any one of a number of radicals and the resulting analogues of sulfanilamide will have different antibacterial, pharmacologic, and physical characteristics; these of course have a selective bearing upon their medical usage.

An important chemical reaction which affects the therapeutic usefulness of the sulfonamides occurs within the body, and is known as acetylation. This process occurs principally in the liver, and consists of the substitution of an acetyl ($-COCH_3$) group for one of the hydrogens of the amino group attached directly to the benzene ring. This acetylated form per se generally appears to be therapeutically inactive in the body, but has an important bearing upon the pharmacologic properties and toxicity of the drug. Sulfapyridine, for instance, is conjugated to form the acetyl derivative to a much higher degree than either sulfanilamide, sulfathiazole, or sulfadiazine. Also in the case of sulfapyridine and certain others of the sulfonamides, the acetylated form is more insoluble than the free form. There is, therefore, a tendency for the conjugated compound to form a precipitate of crystals in the urine which may attain sufficient size to cause an actual occlusion of the kidney, pelvis, or ureter. However, in the case of still other sulfonamides, for instance, sulfadiazine, the acetylated form is more soluble in urine than is the free form.

Of the many thousands of compounds which have been synthesized on the basis of these broad chemical principles, a relatively few are of practical importance at the present time. These possess a considerable degree of bacterial specificity, and it therefore is important that the selection of a particular drug for therapeutic purposes be made

A portion of the material dealing with antibiotics was read with additions, before the Scientific Section of the Proprietary Association of America, New York, N. Y., December 5, 1945, by invitation.

Assistant Surgeon, New York Post-Graduate Medical School and Hospital.

The accumulation of much of the data reported herein with respect to the antibacterial and sensitizing properties of tyrothricin was made possible by a grant from the Johnson and Johnson Research Foundation.

on the basis of precise bacteriologic information. Frequently the nature of the etiologic agent may be apparent from the clinical aspects of the disease; when this is not so, diagnostic cultural procedures should be undertaken whenever possible, and the susceptibility of the causative organism to the contemplated therapeutic agent determined for maintenance of adequate dosages.

In addition to the bacterial specificity of the drug, one must consider the potential toxicity of the compound to the human organism under the pertaining pathophysiological conditions. The sulfonamides, in general, are relatively toxic—some more so than others—but all may cause reactions. From the standpoint of toxicity, therefore, certain selections may be made; the selected drug must be compatible with the bacteriologic circumstances, or its administration would prove ineffective. Other important factors influencing selection are the rapidity of absorption and excretion of the drug, and the degree of acetylation, both of which have a primary bearing upon the dosage and frequency of administration.

There are few contraindications to the use of other necessary drugs concomitant with the sulfonamides. It was thought at first that administration of saline laxatives and sulfanilamide tended to produce sulfhemoglobinuria or methemoglobinuria, but there seems to be little supporting evidence for this belief (46). Nor does there seem to be any reason for regulating the diet simply because a sulfonamide is being given, since no support can be found for the impression, for instance, that the presence of eggs in the diet facilitates the production of sulfhemoglobinuria.

Patients who are receiving sulfonamides should not be subjected to ultraviolet therapy, or exposed to strong sunlight. There appears to be no contraindication to the use of inhalation anesthesia in patients receiving the sulfonamides, nor do these drugs appear to affect adversely the patient's response to surgical procedures.

It has been our experience that surgical patients tolerate the administration of sulfonamides with fewer toxic manifestations if an adequate vitamin C intake is maintained. This is true particularly in patients receiving general anesthetics, as inhalation anesthesia may produce a serious vitamin C deficiency (Beyer, 6).

The sulfonamides commonly used for therapeutic purposes may be divided into those which are readily absorbed from the gastrointestinal tract, such as sulfanilamide, sulfathiazole, sulfadiazine, and sulfamerazine, and those which are poorly absorbed and whose action is largely limited to the intestinal tract, such as sulfaguanidine (actually,

as shown by Firor and Poth, and by Streicher [66], considerable amounts of this compound are absorbed at therapeutic dosage levels), sulfasulidine (succinylsulfathiazole), and sulfathalidine (phthalylsulfathiazole).

SULFANILAMIDE

Sulfanilamide (para-aminobenzene sulfonamide), the first sulfonamide to attain wide use in this country, is effective by mouth and is readily absorbed from the gastrointestinal tract, significant blood levels being attained an hour following a single large dose. It diffuses rapidly into all of the body tissues and fluids, and during parturition the concentrations of the drug in the maternal and fetal circulations are equivalent. Between 10 and 15 per cent of the circulating drug is in the acetylated form; over 90 per cent, of which from 25 to 50 per cent is conjugated, is excreted in the urine. It is important to realize that the amount of drug excreted is directly proportional to the amount of urine secreted; the dosage and administration of fluids may be so adjusted that a balance is maintained easily by frequent administration of the drug. The compound is almost entirely excreted from the body within 48 hours following withdrawal.

Sulfanilamide is particularly effective against beta hemolytic streptococcal infections, but, because of lower toxicity, sulfadiazine may be preferable. In cases of streptococcal bacteremia, sulfanilamide has markedly reduced the morbidity and mortality when given in doses sufficient to produce a blood level of from 10 to 15 mgm. per 100 c.c.

Streptococcal infection of the peritoneum is most common in young children. The infection may not infrequently appear to be endogenous in origin, but is more commonly seen as the main component of a mixed infection following some surgical catastrophe, such as a ruptured appendix. Two therapeutic approaches are desirable. Sufficient sulfanilamide should be given by mouth to maintain a blood level of at least 10 mgm. per 100 c.c., and, when surgical intervention is carried out, the topical application of sulfanilamide powder to the involved peritoneal site may prove of value in many cases. All other recognized therapeutic measures should, of course, be carried out concomitantly.

In the treatment of mastoiditis the sulfonamides must be used with care, since a spreading lesion may easily be masked. When actual suppuration has occurred, immediate recourse should be made to surgical intervention. Nevertheless, it would appear that the general use of the sul-

fonamides in the treatment of the above mentioned conditions has greatly lessened the incidence of surgical mastoiditis.

Streptococcal pneumonia and empyema respond favorably to this drug, but sulfadiazine has been shown to be highly effective, and is probably to be preferred because of its lower toxicity.

In cellulitis and lymphangitis, which are usually due to streptococcal invasion of the tissues, sulfanilamide is effective; but again it must be pointed out that sulfadiazine and sulfamerazine appear to be at least as effective and are less toxic.

Good results have been reported in the treatment of streptococcal osteomyelitis by the oral and local use of sulfanilamide. High blood levels should be maintained for 2 weeks or longer, and all local suppurations should be incised and drained.

The effectiveness of sulfanilamide against the extremely heterogeneous group of infections caused by alpha hemolytic streptococci is questionable. although Spink has shown that the drug is bacteriostatic for some strains. One is, therefore, justified in administering sulfanilamide for a reasonable period of time, but, if no improvement occurs, penicillin should be tried.

Sulfanilamide has little effect against anaerobic streptococcal infections when administered orally. It has been observed, however, that the local bacteriostatic effect of sulfanilamide may be potentiated by combination with zinc peroxide. This form of therapy, in conjunction with adequate surgical procedures, is frequently effective; if not, penicillin should be used, possibly in combination with either sulfanilamide or sulfadiazine.

We (2) and others (30, 31, 33, 58, 64, 67) have reported good results with sulfanilamide in the acute or early phases of lymphogranuloma venereum, but sulfathiazole also has proved effective. However, sulfadiazine gives promise of being more satisfactory than either drug because of lower toxicity.

When sulfanilamide is to be used in the treatment of severe infections, it is given in an initial dose of 0.10 gm. per kilogram of body weight (46). This is followed by a total daily dosage of 0.10 gm. per kilogram of body weight, divided into 6 doses, and administered every 4 hours until the temperature has remained normal for at least 7 days. In hemolytic streptococcal otitis media, mastoiditis, or osteomyelitis, the drug should be continued in somewhat smaller doses for at least 10 days after a clinical cure has been obtained. It is considered that a blood level of from 10 to 15 mgm. per 100 c.c. is adequate in most cases. In order to attain this it is very rarely necessary to exceed a total

dose of 13 gm. during the first 24 hours; as a rule, 10 gm. suffice in the average adult.

Sulfanilamide should be given by mouth whenever possible, but, if necessary, it can be freshly prepared, 1 per cent in saline solution, and given subcutaneously. One-half of the total calculated 24 hour dose is given initially, the remainder being divided between 2 subsequent doses given at 8 hour intervals.

SULFAPYRIDINE

Sulfapyridine (2-[p-aminobenzenesulfonamido]-pyridine) diffuses readily into all bodily tissues and fluids, and the concentration found in the spinal fluid is approximately 65 per cent of that in the blood. A considerably higher percentage of the drug is acetylated within the body than is the case with sulfanilamide, and may amount in some cases to as much as from 60 to 75 per cent of the total circulating drug.

Sulfapyridine is excreted, largely in the acetylated form, somewhat more slowly than is sulfanilamide by the kidneys. Acetylated sulfapyridine is less soluble than free sulfapyridine; and when present in sufficiently high concentration, there is a tendency for the compound to form crystals in the urine, which may result in hematuria, renal colic, or obstruction.

In addition to its specific bacteriostatic action, sulfapyridine exerts a rather marked antipyretic action, quite apart from that which might be expected from alleviation of the specific infectious condition for which the drug is being given. This may be quite confusing at times, and should not be the cause of overoptimism when this drug is used in the treatment of a severely ill patient.

Because of the availability of less toxic and more effective compounds, we have abandoned completely the use of sulfapyridine except in cases of anthrax. In this condition sulfapyridine appears somewhat more effective than other sulfonamides when given in doses of 4 gm. initially, followed by 1 gm. every 4 to 6 hours. However, it is important to be alert for toxic manifestations, especially those involving the urinary tract.

SULFATHIAZOLE

Sulfathiazole (2-[p-aminobenzenesulfonamido]-thiazole) is about one-tenth as soluble as sulfanilamide, but is rapidly absorbed from the intestinal tract when administered by mouth, the maximum concentrations being reached in from 3 to 6 hours. However, it is excreted very rapidly by the kidneys unless renal function is impaired, so that the maintenance of adequate blood levels is sometimes difficult. The urinary complications

encountered following the administration of sulfathiazole include gross and microscopic hematuria, azotemia, and anuria. These effects may be due to the formation of acetyl sulfathiazole crystals and calculi in the renal tubules, pelvis, or ureters, but in some patients seem to be the result of a direct toxic effect of the drug on the renal epithelium. It is therefore especially important, when this drug is used, to maintain a urinary output of at least 1,000 c.c. per day.

Sulfathiazole is useful in the treatment of staphylococcal infections and some infections of the urinary tract due to the *Escherichia coli*.

Since sulfathiazole is only slightly soluble, it must be administered orally. However, when oral administration is impossible, or satisfactory concentrations of the drug cannot be maintained by this route, the sodium salt may be given intravenously. When so given, the dosage is based on 0.06 gm. per kilogram of body weight of the sodium salt made up in a 5 per cent solution of sterile, freshly distilled water. Subsequent doses are based upon 0.03 gm. per kilogram of body weight given at 6 hour intervals.

In the treatment of large boils or carbuncles, the initial dose for adults should be 4.0 gm., followed by 1.0 gm. every 4 hours, day and night, for from 5 to 7 days. In diffuse staphylococcal cellulitis, lymphangitis, or acute osteomyelitis, 4.0 gm. should be given as an initial dose, to be followed by doses of 1.5 gm. every 4 hours, day and night, as long as evidence of a spreading infection continues. Then the dose is reduced to 1.0 gm. every 4 hours, day and night, and continued as indicated. In staphylococcal bacteremia the initial dose for adults should be 4.0 gm. followed by 1.5 gm. every 4 hours, day and night, until the temperature has been normal for 48 hours. Then the dose may be reduced to 1.0 gm. every 4 hours, day and night, for 14 days, at which time the dose is further reduced to 0.5 gm. every 4 hours, day and night, and continued for a minimum of 14 days. In severe staphylococcal infections in children, the initial dose should be calculated on the basis of 0.2 gm. per kilogram of body weight (up to 20 kgm. of weight). The total daily dose is calculated on the same basis, and should be divided into 6 parts, given at 4 hour intervals, day and night, until the temperature has been normal for 48 hours. Then each dose may be reduced by one-third and treatment continued at this level for 14 days, at which time the current dose may be reduced by one-half.

In staphylococcal bacteremia there is a great possibility that a relapse will occur unless prolonged treatment with the drug is employed.

In chronic staphylococcal infections, such as osteomyelitis, it is to be remembered that surgical measures, both supportive and operative, must be used whenever indicated, and in our opinion both sulfadiazine and penicillin are more useful chemotherapeutic agents in this condition than is sulfathiazole. Surgical drainage of purulent foci must be effected, because while drugs may halt the invasive manifestations of staphylococcal infection, no drug by itself will cure areas of localized infection, and a flare-up in such areas is likely to occur if they are not properly drained.

SULFADIAZINE

Sulfadiazine (2-(p-aminobenzenesulfonamido)-pyrimidine) is considerably less toxic than sulfathiazole and, although it is readily absorbed from the gastrointestinal tract (51), it is excreted slowly. Studies of the distribution of the drug within the body have shown that it is present in the peritoneal and pleural fluids in approximately the concentration found in the blood; in the cerebrospinal fluid the concentration is approximately 50 per cent of the blood concentration.

This compound is highly effective in the treatment of pneumococcal, streptococcal, staphylococcal, and meningococcal infections, erysipelas, acute infections of the urinary tract, especially those due to susceptible strains of the *Escherichia coli*, and acute gonorrheal urethritis and arthritis (24). Chronic urinary tract infections do not respond readily to sulfadiazine; especially stubborn are chronic *Escherichia coli* and *Bacillus proteus* infections. Sulfadiazine causes considerably less nausea and other side reactions than does sulfathiazole. The precipitation of acetylsulfadiazine crystals in the urinary tract may be largely avoided by the administration of sufficient alkali by mouth to maintain a slightly alkaline urine. It has been stated (29) that the amounts of sulfadiazine and acetylsulfadiazine dissolved in normal urine at pH 7.5 are twenty times greater than at pH 5.0. The simplest way to test urine clinically for alkalinity is by means of nitrazine paper. To produce consistently alkaline urine requires the daily administration of from 12 to 24 gm. of sodium bicarbonate (49, 60). The administration of sodium bicarbonate in amounts equivalent to the dosage of sulfadiazine is said to reduce the incidence of crystalluria by 60 per cent (49). We have found that an average dose of 1 gm. of sodium bicarbonate every 4 hours¹ satisfactorily reduces the danger of urinary complications, although there is some evidence that both sulfa-

¹The sodium bicarbonate is routinely given in doses equivalent to the amount of sulfadiazine.

diazine and sulfamerazine may exert a direct nephrotoxic effect, quite aside from the question of alkalization (1). Ohnysty and Wolfson have suggested the daily administration of 12 gm. of potassium bicarbonate on the excellent basis of avoiding the complications of sodium retention in patients potentially subject to cardiac decompensation, and as a means of increasing the urinary output. Rohr and Christopher (60) have found that immediate alkalization may be obtained in surgical patients unable to take oral medication by the daily intravenous administration of 1,000 c.c. of one-sixth molar sodium *r*-lactate.

The administration of sulfadiazine should be directed toward the maintenance of a blood concentration of 10 mgm. per 100 c.c., and the attainment of this level as rapidly as possible (63). The initial dose is calculated on the basis of 0.10 gm. of sulfadiazine per kilogram of body weight. Thereafter, 1 gm. of the drug is given every 4 hours until the temperature has been normal for 3 days.

Circumstances frequently arise which make it impossible to administer a sufficient amount of the drug to severely ill patients by mouth to raise the blood concentration to a therapeutically desirable level. In these instances the sodium salt is administered intravenously in a concentration of 5 per cent in sterile distilled water; because of the marked alkalinity of this solution, care must be taken not to allow any of the material to leak into the perivascular tissues.

In the combined parenteral and oral method of therapy the initial dose of sodium sulfadiazine is based on 0.60 gm. per kilogram of body weight. The maintenance dose of 1 gm. of sulfadiazine every 4 hours then is given orally.

If it is necessary to resort to parenteral therapy alone, the initial dose is the same as for the combined type, but the maintenance dose is calculated on the basis of 0.05 gm. per kilogram of body weight. This dose is administered intravenously every 12 hours. Frequent determinations of the concentration in the blood should be made. It is inadvisable to exceed a blood concentration of 20 mgm. per 100 c.c., and a change should be made to the oral route as early as possible.

In infants and children the initial doses for both oral and parenteral administration are calculated in the manner already outlined. This is true also of the maintenance dose of sodium sulfadiazine. The total daily dose of sulfadiazine is calculated on the basis of 0.10 gm. per kilogram of body weight and is divided into 6 parts given at 4 hour intervals until the temperature has been normal for 48 hours.

For the treatment of mild and moderately severe hemolytic streptococcal infections, the initial dose of sulfadiazine is based on 0.05 gm. per kilogram of body weight. The total daily dose consists of 0.10 gm. per kilogram of body weight divided into 6 doses and given every 4 hours until the temperature has been normal for 5 days.

In severe infections the initial parenteral dose of sodium sulfadiazine is based on 0.06 gm. per kilogram of body weight. This is followed by sulfadiazine given orally on the basis of 0.15 gm. per kilogram of body weight per day. The total amount is divided into 6 doses and given every 4 hours until the temperature has been normal for 5 days. The dose then is decreased slowly until the patient becomes ambulatory.

In the treatment of acute or spreading peritonitis, maximum blood levels should be maintained by the intravenous route, in order to avoid administration of the drug by mouth. In many cases it will be desirable to supplement or supplant sulfonamide therapy with the administration of adequate amounts of penicillin. In cases of *escherichia coli* infections, streptomycin would be worth trying if available, possibly in conjunction with sulfadiazine administration.

SULFAMERAZINE

Sulfamerazine (sulfamethyldiazine), *p*-amino-N-2-(4-methyl pyrimidyl) benzenesulfonamide, is similar in its uses and mode of action to sulfadiazine except that comparable blood concentrations are obtained with approximately one-half the amount of sulfamerazine as is required of sulfadiazine (71). The drug is more rapidly and more completely absorbed from the gastrointestinal tract than is sulfadiazine; therefore, it may be given in smaller amounts and, since it is excreted more slowly than is sulfadiazine, less frequently.

The distribution in the body tissues is about the same as that of sulfadiazine, and its over-all toxicity is no greater. The acetylated form of sulfamerazine is more soluble in urine at pH 7 or less than either the free or acetylated forms of sulfadiazine, and free sulfamerazine is more soluble than sulfadiazine in neutral or acid urine. The formation of drug concretions and renal parenchymal injury seem to be less likely to occur with sulfamerazine than with sulfadiazine, if equal blood concentrations of the drug are compared. In the absence of urinary complications, no great advantage seems to be gained by the administration of sodium bicarbonate concomitantly with sulfamerazine since the conjugated form of sulfamerazine is relatively soluble in neutral and acid urine and, as Beyer *et al.* (5) have shown, the

administration of sodium bicarbonate increases the renal clearance of all absorbable sulfonamides by interference with their reabsorption. This effect is more striking in the case of sulfamerazine than in that of sulfadiazine, so that alkalization makes the maintenance of adequate blood levels of sulfamerazine somewhat difficult without significant decrease of the chances of urinary complications.

The statements concerning the bacterial specificity of sulfadiazine are applicable to an approximately equal degree with respect to sulfamerazine.

Another absorbable sulfonamide which is available for essentially the same indications as those outlined for the sulfonamides already discussed is sulfapyrazine (2-sulfanilylaminopyrazine). However, this compound appears to be effective against certain strains of *shigella* paradysenteriae, even when these are resistant to other sulfonamides.

INTESTINAL BACTERIOSTATIC SULFONAMIDES

Of the sulfonamides which are poorly absorbed from the gastrointestinal tract, succinylsulfathiazole and phthalylsulfathiazole have received the most attention, although sulfaguanidine was one of the first of the sulfonamides to be offered clinically for the specific treatment of infectious conditions of the gastrointestinal tract.

SUCCINYL-SULFATHIAZOLE

Sulfasuxidine or succinylsulfathiazole (2-[N-(succinyl sulfanilamide)-thiazole] manifests an extremely low order of toxicity, probably as the result of the fact that it is absorbed from the gastrointestinal tract in extremely small amounts. That the drug possesses a startling ability to lower the coliform count of the stool has been demonstrated in animals and human beings by many investigators (52, 53, 55, 65). Of further importance is the fact that a high concentration of the drug can be maintained in the human intestinal tract, although, due to the low degree of absorption, only extremely low concentrations occur in the blood, rarely exceeding 2 mgm. per 100 c.c. Less than 5 per cent of the total amount of the drug administered by mouth is excreted in the urine. The explanation of the strongly antibacterial action of the drug within the intestinal tract is not clear, since the hypothesis that this is due to the sulfathiazole liberated in the bowel by hydrolysis no longer seems tenable in the light of more recently obtained data concerning the comparative bacteriology of the drug.

To be effective, succinylsulfathiazole must come in contact with all portions of the bowel mucosa;

when this is accomplished, the desired effect is usually attained in from 3 to 5 days. In the presence of enterostomies, diversion of the fecal stream, or exclusion of various segments of the bowel by one means or another, the drug must be introduced directly into each isolated segment by the most appropriate means; otherwise it will not be possible to reduce the bacterial count to satisfactory levels.

The rationale with respect to the use of the drug preoperatively is quite obvious, since by reducing the potential infectivity of the intestinal contents the chances of incurring a surgical peritonitis are lessened and the possibilities of the patient's recovery thereby enhanced. It must be emphasized, however, that chemotherapy should be considered only as a helpful adjunct to careful surgical technique and adequate surgical care; no chemotherapeutic advance, however brilliant, should be allowed to vitiate well established surgical principles.

When the drug is administered postoperatively, a low bacterial count of the intestinal contents is maintained, with the result that there is little distention, and gas pains, nausea, and vomiting are reduced.

For preoperative preparation the following regimen has been suggested by Poth (52) for all patients who do not have complete intestinal obstruction. The patient is placed on a low residue diet, and receives an initial dose of succinylsulfathiazole of 0.25 gm. per kilogram of body weight. Thereafter maintenance doses are given on the basis of 0.25 gm. per kilogram per day, divided into 6 equal parts and administered every 4 hours. No enemas or purgatives should be used. In the course of from 3 to 7 days the stools become small in bulk, semifluid, and relatively odorless. A bacteriologic examination of the feces will show a marked decrease in the coliform organisms. At operation the bowel is found to be collapsed and is relatively free from feces and gas. Operation may be performed on the open colon without undue risk of peritonitis or local abscess formation provided well established surgical principles are scrupulously followed.

The postoperative maintenance level is 0.25 gm. of drug per kilogram of body weight per day, and treatment is continued for from 1 to 2 weeks, according to the convalescent response of the patient.

Everett, Scott, and Steptoe (23) found succinylsulfathiazole effective in the treatment of urinary tract infection due to *escherichia coli* when administered in daily doses of 0.25 gm. per kilogram of body weight. Some of their cases in which

this drug proved effective had been refractory to therapy with other sulfonamides and mandelic acid. The authors suggest that the probable mode of action of succinylsulfathiazole in clearing urinary tract infections due to *Escherichia coli* seems to be the elimination of the source of the infection from the large bowel, which permits the tissues of the urinary tract to overcome the infection by means of their own biological mechanisms. This suggestion provides an interesting line of investigation but requires confirmation by other workers.

Succinylsulfathiazole is of considerable value in safeguarding the patient during the preoperative and postoperative periods from the hazards of infections which are the accompaniment of radical intestinal surgery, but let it never be forgotten that there is no substitute for painstaking technique and surgical acumen.

PHTHALYLSULFATHIAZOLE

Sulfathalidine, or phthalylsulfathiazole, is a dicarboxylic derivative of sulfathiazole with action similar to that of succinylsulfathiazole, but it appears to manifest a greater degree of antibacterial activity against the coliform organisms of the intestinal tract at considerably lower dosage levels. Poth and Ross (56) have shown that this drug "is absorbed sparingly from the gastrointestinal tract, that it maintains low concentrations in the blood (0.1 mgm. to 1.5 mgm.), and that it is rapidly excreted in the urine;" it appears that the new drug has from two to four times the bacteriostatic activity of succinylsulfathiazole and that it causes no toxic symptoms in man.

Phthalylsulfathiazole appears useful in the treatment of ulcerative colitis (66, 57, 3) and regional ileitis (33). It has not been shown to be effective as has succinylsulfathiazole in the treatment of dysentery due to shigella dysenteriae and the Flexner and Sonne types of paradysentery (54, 62, 14).

Phthalylsulfathiazole has been found effective as a prophylactic agent in the suppression of infections occurring in connection with surgical procedures upon the intestinal tract (58, 63, 66), but both Cave and Streicher (66) believe that succinylsulfathiazole is more satisfactory than phthalylsulfathiazole in the preoperative preparation of surgical patients.

The dosage originally recommended for the latter compound varied from 0.05 to 0.1 gm. per kilogram of body weight per day. The evidence presented independently by Cave and Streicher, both of whom have had extensive experience with the drug, suggests that a total daily dose of from 3 to 6 gm. is adequate, and that amounts in excess

of these quantities are both detrimental and wasteful. We are substantially in agreement with these statements.

PROPHYLAXIS OF WOUND INFECTIONS

One of the greatest disappointments in the field of sulfonamide therapy has been the failure of this group of compounds to fulfill the high hopes originally held for them as prophylactic agents for the control of wound infections. This subject was intensively investigated by Meloney (48) who studied a total of 2,191 cases, including 926 wounds of the soft parts, 674 compound fractures, and 591 burns, treated at nine different centers where records were kept in a uniform manner for a subsequent analysis of all. The cases included patients who received the sulfonamides systematically alone, locally alone, or by both methods.

The data thus obtained afforded little evidence that sulfonamide treatment reduced the frequency of infection. Nevertheless, as has been emphasized (21), it is recognized that sulfonamides may prevent a lethally extensive spread of the infection. It is evident, however, that what the sulfonamides will *not* do is to reduce the liability to either trivial or serious infection of the wound itself. Routine prophylactic administration of sulfonamide, therefore, does not appear to serve any useful purpose, and the baptism of every wound with a sulfonamide, regardless of character or location, certainly is to be decried. As Meloney observes, "All of the results seem to indicate that the main dependence of the surgeon in the prevention of infection both in civilian accidental wounds and in the war wounds must be placed upon the well known principles of the surgical care of contaminated wounds: namely, the removal of the devitalized tissue and the contamination, and the rapid restoration of the normal physiology of the part involved. The use of the sulfonamides can in no measure make up for this."

ANTIBIOTIC AGENTS

That class of therapeutic agents referred to as the antibiotics has become of dramatic interest within the last few years, although the existence of such substances has been known for a long time. Pasteur and Joubert, as long ago as 1877, were aware that certain airborne organisms inhibited the growth of the anthrax bacillus, and they even suggested that this phenomenon of antibiosis might be useful in treating certain infections. The first serious attempt to apply this principle was made by Emmerich and Loew in 1899, with a substance known as pyocyanase, which was derived from the *Pseudomonas aeruginosa* (bacillus

pyocyanus) and inhibited the growth of diphtheria, cholera, typhoid, and plague organisms. However, in spite of the pursuance of similar lines of investigation by many workers, no purified product of therapeutic usefulness was isolated until the preparation of tyrothricin in 1939 by Dubos (16, 17, 18, 20, 41, 42). Ten years previously, Fleming (26) of St. Mary's Hospital in London had reported the discovery of penicillin, but actual isolation of this substance in a form suitable for clinical use was not reported until August, 1940, as the result of a co-operative investigation under the leadership of Sir Howard W. Florey at the Sir William Dunn School of Pathology at Oxford, England (30).

Subsequently much attention has been directed toward the isolation of other antibiotic substances. Since the activity of both tyrothricin and penicillin had been shown to be mainly against gram-positive organisms, particular interest lay in isolating an agent which would be effective against gram-negative bacteria.

In 1941, Waksman, Woodruff and Horning (70) mentioned a new substance which they were in the process of isolating from the soil organism *actinomyces lavendulae*, and which they termed "streptothricin." This substance possessed considerable activity against gram-negative organisms, but when administered subcutaneously or intravenously to experimental animals frequently resulted in early or delayed death.

In January, 1944, Schatz, Bugie, and Waksman announced the isolation of a substance derived from another soil organism, *actinomyces griseus*, which they termed streptomycin. This differed from streptothricin in that the pure material was less toxic and possessed considerable activity against gram-negative organisms.¹

Exploitation of the scientific possibilities of the antibiotic field still is in a relatively preliminary stage, but certain generalizations have become apparent which are important with respect to the effective use of such agents as are already available.

Antibiotic substances manifest a marked selectivity, and the optimal conditions for each agent vary widely; the mechanism of action of the various members of this class of substances also is variable. Some substances act by interfering with bacterial cell division, some affect bacterial respiration, and some interfere with the use of certain essential metabolites by the bacterial cell, through a mechanism of either replacement or combination (69).

¹Streptothricin, although more toxic than streptomycin, also is more active against many gram-negative organisms. On this basis, it may prove more promising than streptomycin for local application.

Although a great many antibiotic substances are known, only three are of practical clinical utility at the present time. These are penicillin, streptomycin, and tyrothricin. Each possesses certain unique characteristics which define its specific therapeutic sphere.

PENICILLIN

Penicillin is an extremely active and essentially nontoxic agent against many of the pathogenic gram-positive bacteria, including the pneumococcus, streptococcus, staphylococcus, and clostridia, certain gram-negative organisms, notably the gonococcus and meningococcus, and certain spirochetes, including the causative agent of syphilis. Because of its relative instability, its principal use is by means of the parenteral administration of freshly prepared solutions. Fairly stable preparations of penicillin intended for oral administration are available, but, as McDermott and his associates (8, 47) have shown, the oral dosage is approximately five times that required to maintain a given blood level by parenteral administration. High unitage beeswax and vegetable oil mixtures are available for intramuscular injection, but in our hands these have proved cumbersome for routine use because of the fact that the least amount of moisture in the syringe will solidify the material and cause a great deal of difficulty.

Although penicillin is available now in forms especially designed for oral, topical, and parenteral administration, most infections of a surgical nature require treatment by the latter method. The conditions falling into this category, and for which penicillin has been found to be the drug of choice, have been listed by Keefer *et al.* (44) as follows:

1. All staphylococcal infections with and without bacteremia:
 - Acute and chronic osteomyelitis
 - Carbuncles—soft tissue abscesses
 - Meningitis
 - Cavernous or lateral sinus thrombosis
 - Pneumonia—empyema
 - Carbuncle of the kidney
 - Wound infection—burns
 - Endocarditis
2. All cases of clostridial infections:
 - Gas gangrene
 - Malignant edema
3. All hemolytic streptococcal infections with bacteremia and all serious local infections:
 - Cellulitis
 - Mastoiditis with intracranial complications, i.e., meningitis, sinus thrombosis, and so on

Pneumonia and empyema

Puerperal sepsis

Peritonitis

Endocarditis

4. All anaerobic streptococcal infections:

Puerperal sepsis

Localized infections elsewhere

5. All pneumococcal infections of the meninges, pleura, and endocardium,¹ and all cases of sulfonamide-resistant pneumococcal pneumonia.

Penicillin is of questionable value in mixed infections in which the predominating organism is gram-negative; nevertheless, it may be tried in desperate cases. These conditions include ruptured appendical abscess with peritonitis, liver abscess, urinary tract infections due to *Escherichia coli*, and possibly rat bite fever due to the streptobacillus moniliformis.

The dosage varies according to the circumstances of each case, but a total daily dosage of 100,000 units should be considered minimal, while serious infections require several times this amount. For intravenous injection, solutions may be prepared containing from 10,000 to 50,000 units per cubic centimeter, or suitable amounts dissolved in the standard saline or glucose infusion solutions. For intramuscular injection, concentrations of from 10,000 to 50,000 units per cubic centimeter of isotonic saline solution are used in order to keep the total volume administered as small as possible.

Since penicillin is excreted extremely rapidly in the urine, administration should be so planned as to maintain a therapeutic concentration of the drug in the blood stream at all times. Beyer *et al.* (4) have shown that the intravenous administration of sodium para-aminohippurate is capable of increasing the plasma concentration of penicillin over that which is procured when penicillin is administered alone. A two-fold increase in the plasma concentration of penicillin was obtained at a para-aminohippuric acid plasma concentration of 7.9 mgm. per 100 c.c., the lowest concentration which was used in the reported experiments. A five-fold increase in the penicillin level was noted at a para-aminohippuric acid plasma concentration of from 47.7 to 46.9 mgm. per 100 c.c. These investigators point out that it is possible to "effect a considerable economy of penicillin or maintain plasma concentrations of the antibiotic agent not heretofore practicable, when penicillin together with sodium para-aminohippurate is administered continuously by venoclysis."

¹For this listing we would add pneumococcal peritonitis, which is by no means a rare occurrence in children.

STREPTOMYCIN

Streptomycin, although manifesting some activity against certain gram-positive organisms, is principally effective, as has already been indicated, against a relatively limited number of gram-negative organisms. It is stable in the dry state at room temperature for at least from 6 to 9 months when the moisture content does not exceed 3 per cent. Present standards require that the minimum potency of the product intended for parenteral use should be equivalent to not less than 20 per cent of pure streptomycin base per gram. In other words, 5 gm. of streptomycin for parenteral use should be equivalent to not less than 1 gm. of crystalline streptomycin base.

Until the question of toxicity has been more fully clarified and our knowledge concerning the pharmacology and clinical use of this substance has been considerably broadened, it would appear that there are no advantages to intravenous injection which would outweigh the potential disadvantages, and therefore it has been recommended that the intravenous route be avoided in so far as possible. The desirable routes of administration are intramuscular (either intermittent or continuous administration), subcutaneous, intrathecal, intraperitoneal, and intrapleural. The drug has also given striking results when administered by nebulization in combination with penicillin, against both gram-positive and gram-negative flora. For parenteral use solutions should be prepared so that each cubic centimeter contains not less than the equivalent of 50 mgm. of crystalline streptomycin base, in order to keep the volume of each injection as low as possible.

The usefulness of streptomycin in the treatment of typhoid infections in human beings has not been confirmed, and hopes for its effectiveness in the eradication of the typhoid carrier state have been doomed to disappointment up to this time. Zint, Flippin, Nichols, Wiley, and Rhoads (7) however, have shown that streptomycin, when given by mouth, is retained in the intestinal tract and acts as an excellent intestinal antiseptic, and it may prove to be better than the sulfonamides in this respect. Streptomycin exhibits considerable activity in the control of tuberculosis in guinea pigs, but its effective role against the disease in human beings has yet to be substantiated by clinical demonstration in a statistically significant series of cases. Such a study now is in the process of organization upon a large scale. For the present at least, it is urged that streptomycin be used only after careful consideration of the potential benefits to be expected and that its use be limited to cases of infection by pas-

teurella tularensis, bacillus proteus, escherichia coli, pseudomonas pyocyaneus, pasteurella cholerae, pasteurella pestis, hemophilus influenzae (meningitis), brucella melitensis, Friedlaender's bacillus (klebsiella), salmonella, and certain cases of tuberculosis involving the genitourinary tract, the gastrointestinal tract, the meninges, pleura, and peritoneum. The benefit to be expected in tuberculous systemic infections should be anticipated with reserve.

The dosage varies from the equivalent of from 1 to 3 gm. of crystalline streptomycin base per day, the average dosage being the equivalent of 1 gm. a day. It need not be injected more frequently than every 4 to 6 hours because of the fact that it is excreted more slowly than penicillin. The average single dose is from 0.1 to 0.2 gm. or more as governed by the exigencies of the case. Not infrequently an early histaminelike reaction may be noted, characterized by flushing of the face, nausea, vomiting, headache, deafness, or faintness. As a rule, this type of reaction yields readily to the administration of epinephrine. A moderate rise in temperature usually follows each injection. Delayed reactions also may occur, but as little pure material has been available for study, final conclusions concerning the toxicity of this substance may not yet be drawn.

TYROTHRIN

One feature which penicillin and streptomycin have in common is that they are antibiotics of which the therapeutic effect is achieved principally by systemic administration; this differentiates these substances from tyrothricin, which, for reasons to be discussed, is used only for topical application, and never parenterally or orally. This characteristic aroused our interest when it became apparent, on epidemiological grounds, that the topical use of sulfonamides, and possibly of penicillin, by large masses of our population was potentially hazardous. Because tyrothricin appeared to offer promise as a therapeutic improvement over the sulfonamides and certain other antibacterial agents for topical application, and a means of avoiding the dangers possibly inherent in the indiscriminate use of the sulfonamides and penicillin, the desirability of utilizing this agent for purposes of topical antisepsis was investigated.

That tyrothricin, which is a mixture of two substances (gramicidin and tyrocidine), exerts an antibacterial action against a large number of organisms has been known for a long time, although no study defining the exact extent of the bacterial spectrum for tyrothricin has, as yet,

been reported in the literature. Unfortunately, most of the published reports concern themselves with a limited group of organisms and none presents a comprehensive review of the problem. The data obtained by the different investigators are not always comparable since the mediums used and the cultural conditions under which the tests were performed varied widely.

In co-operation with Dubos, a systematic survey of the effect of gramicidin and tyrocidine on a large variety of microbial species under standardized conditions was undertaken. It was found that the antibacterial action of gramicidin is unaffected by any concentration of serum albumin; in fact, as observed by Dubos (10), this activity seems to be appreciably increased in this medium. On the contrary, tyrocidine, the other component of tyrothricin, is, like other antiseptics, largely inhibited by albumin. Gramicidin does not kill the spores of aerobic or anaerobic sporulating bacilli, but only inhibits their multiplication. In the case of a few nonsporulating species (Lancefield group D streptococci, in particular) the effect of gramicidin is essentially bacteriostatic. In general, however, the bactericidal level is very close to the bacteriostatic level and this is particularly true in the case of the pathogenic species which we have tested. Although this survey is far from complete, the results at the present time permit a few statements which have been summarized elsewhere (35).

Concerning the antibacterial effect of tyrothricin *in vivo*, as studied under clinical conditions, there is abundant evidence. Suffice it to say that its successful clinical use has been reported by a number of investigators in such conditions as localized infections (59), chronic ulcers of the extremities (36, 45), mastoid cavities (13), empyema (59), and certain pyodermatoses (59), and as an irrigating solution in the treatment of sinusitis (13), eye infections (34), and various types of urinary bladder infections (59), and in the preparation of infected wounds for skin grafting (37). The Russians (28) have used a similar though considerably less active material, which they call "gramicidin S," in the treatment of infected gunshot wounds, osteomyelitis, and similar conditions, with considerable reported success.

The optimal therapeutic concentration of tyrothricin, with consideration of the local tissue toxicity and the maximal antibacterial effect, as originally demonstrated by Herrell and Heilman (37, 38, 39, 40), is in the neighborhood of 500 micrograms per cubic centimeter, and this concentration is widely used today for therapeutic application.

On the basis of data obtained from experiments designed to demonstrate the antiseptic activity of tyrothricin *in vivo*, published elsewhere (35), it is clear that tyrothricin exerts a rather remarkable local antiseptic effect, and in inoculated wounds¹, sterilization or reduction of the infection to a point where it was readily cared for by the tissues' own biological mechanisms was achieved.

Many antibiotic agents have proved impractical because of toxicity, even though some have possessed a high degree of antibacterial activity. That tyrothricin possesses a remarkably low local tissue toxicity was first demonstrated by the tissue culture studies of Herrell and Heilman (38, 39, 40).

The only striking toxic manifestation of tyrothricin is its hemolytic effect upon the red blood corpuscles when the material is injected experimentally into animals by the intravenous route. This phenomenon constitutes the principal reason that tyrothricin cannot be used parenterally; however, it is of no moment whatsoever when tyrothricin is used topically or in the treatment of body cavities not directly connected with the circulatory system, or in the treatment of open wounds. Even in the latter case, should active bleeding be present, no absorption of the tyrothricin could be expected, nor would any untoward effects be anticipated, since whatever tyrothricin were present would be washed away by the flow of blood before any absorption into the blood stream could occur. In any event, the amounts of tyrothricin present would be far too small to exert any untoward effect even if actually injected intravenously into a small experimental animal.

Grolnick (32) has exhaustively studied the question of whether tyrothricin is capable of causing sensitization. In 171 subjects on whom a solution of tyrothricin containing 1, 2, 5, or 10 mgm. per cubic centimeter had been applied by patch test for a 2 day period, there was no evidence of primary irritation. Twenty-five subjects who had been treated by a 7 day application of a solution containing 10 mgm. per cubic centimeter did not become sensitized to tyrothricin. Finally, sensitivity to tyrothricin failed to develop in 41 subjects who had been given repeated applications with adhesive compresses impregnated with tyrothricin over a prolonged period.

Keeler (43) found no positive reactors in 105 patch tests, and Cooke and Finkelstein (12) tested

a total of 82 subjects without observing evidence of sensitization.

It may be concluded with reasonable assurance, therefore, that although sensitivity is not uncommon in the case of the sulfonamides, penicillin, certain commonly used surface antiseptics, and possibly streptomycin, tyrothricin has not produced sensitization of the skin under the conditions of the experimental studies so far carried out, and if it occurs clinically, experience would seem to be sufficiently large to warrant the conclusion that it must be very rare.

Tyrothricin is available for topical application in the form of ointments, impregnated gauze dressings, and concentrates for preparing solutions. From the standpoint of topical application, its use should be considered complementary to that of the systemic antibiotics.

CONCLUSIONS

It is difficult, in summary, to lay down set rules stipulating the use of specific drugs in given instances, since circumstances so largely govern cases.

In general, sulfonamides in pneumococcal and aerobic streptococcal systemic infections may be used except in gravely ill patients, for whom we prefer maximal doses of penicillin with or without a sulfonamide. In serious staphylococcal infections, penicillin should be used. Of the absorbable sulfonamides, we prefer sulfadiazine or sulfamerazine, the latter being preferable in children because of smaller and less frequent dosage.

In urinary tract infections, especially those due to susceptible strains of *Escherichia coli*, sulfadiazine appears to be the agent of choice unless streptomycin is available and the infecting bacterial strain is susceptible to that antibiotic.

In lymphogranuloma venereum, sulfadiazine is effective in early cases but penicillin is contraindicated.

In clostridial infections, penicillin must be used promptly and in maximal dosage together with antitoxin and definitive surgery. Reliance should not be placed on sulfonamides alone in this condition.

For the preoperative preparation of patients for intestinal surgery, succinylsulfathiazole is to be preferred despite the mechanical drawback of the large number of tablets required for proper dosage. This drug gives an added factor of safety in all cases of operative appendicitis, in which peritonitis is of potential consequence. For certain infections of the intestinal tract, such as ulcerative colitis, ileitis, and diverticulitis, phthalylsulfathiazole may be superior.

¹Some wounds were inoculated with 0.25 c.c. of a 10⁻¹ dilution of group C hemolytic streptococci, with these cultures equivalent to about 10,000,000 organisms per cubic centimeter. Other wounds were inoculated with a contaminating concentration of 10⁻³ of staphylococcus aureus.

For topical application, there seems little justification for the continued use of the sulfonamides. Tyrothricin is an excellent agent for this purpose, particularly for the irrigation of empyema cavities and the urinary bladder, since its activity is not decreased in the presence of purulent discharges. The local use of tyrothricin frequently may be combined advantageously with the systemic use of penicillin or the sulfonamides. Tyrothricin also is satisfactory for the treatment of vascular ulcers of the extremities, the preparation of infected areas for skin grafting, and the topical prophylaxis of gram-positive wound infections.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Otte, J.: Thrombophlebitis of the Lateral Sinus (Thromboflebitis del seno lateral). *Rev. otorr.*, 1945, 5: 173.

The most frequent complications of suppurative otitis media in descending order of frequency are thrombophlebitis, leptomeningitis, encephalitis, and brain abscess.

Some authors state that sinus thrombosis is facilitated by an exposure of the sinus in the course of the mastoid operation, but the writer has not observed this complication among more than 100 cases in which the lateral sinus had been denuded.

Thrombophlebitis of the lateral sinus has been denuded.

Various clinical forms according to the intensity of the process, virulence of the pathogenic microorganisms, and resistance of the patient. The main clinical sign is the high temperature with daily remissions. The onset is usually accompanied by chills. As a rule, the general condition of the patient is good in contrast to the seriousness of the disease. The patient does not complain of headaches, there is no mental confusion nor labyrinthian sign, and only a slight meningeal reaction occurs. If a patient with purulent otitis media shows signs of thrombophlebitis and involvement of the brain, intracranial complications, usually in the form of a cerebellar abscess, must be suspected.

While some workers advocate ligation of the internal jugular vein, others do not favor it. The author recommends the ligation for selected cases and believes that penicillin will greatly limit this surgical method.

The author reports 2 cases of typical thrombophlebitis without complications which were treated unsuccessfully with large doses of sulfa drugs and required ligation of the internal jugular vein.

The disadvantage of the ligation is the interference with the blood supply to the brain. In 1 of the author's cases, signs of cerebral involvement in the form of hemiplegia, headache, vomiting, and facial paralysis appeared 15 days after ligation of the jugular vein. A diagnosis of cerebral abscess was made and the patient recovered after operation.

The author describes 3 cases of atypical thrombophlebitis. In 2, a cerebral abscess masked the characteristic symptomatology of thrombophlebitis. In 1 case, thrombophlebitis of the lateral sinus was followed by meningeal signs in spite of ligation of the internal jugular vein and the administration of large doses of penicillin. The autopsy revealed tuberculous meningitis.

As to the diagnosis of thrombophlebitis, intercurrent general diseases can be excluded only by careful clinical examination.

Thrombophlebitis of the left lateral sinus is frequently complicated by a cerebellar abscess, while an infection of the right sinus is more frequently followed by the development of a cerebellar abscess.

As to the treatment, all the diseased tissue must be removed and the involved sinus must be widely exposed. Penicillin should be administered and the jugular vein should be ligated if the septic picture does not subside. If a thrombosis of the bulb develops, Ramadier's resection should be performed.

JOSEPH K. NARAT, M.D.

Clark, H. B., Jr.: A Study of 150 Cases of Fracture of the Upper Jaw in an Overseas Maxillofacial Center. *J. Oral Surg.*, 1945, 3: 286

From a group of injuries of the face and jaws which passed through a maxillofacial center in Italy between the months of April, 1944, and February, 1945, 150 cases of fracture of the maxilla were taken for detailed study. Eighty-five per cent of the patients were injured under battle conditions, 50 per cent suffering injury from mortar and artillery shell fragments, 30 per cent from bullets, 10 per cent from vehicle accidents, 8 per cent from a blow by a fist or blunt instrument, and 5 per cent from falls.

The treatment of these injuries in forward areas was evaluated. Many of the patients requiring intermaxillary fixation had an appliance in place when they arrived at the maxillofacial center. Another group of 23 had no fixation and fixation was accomplished at the center. There was no significant difference in the progress of these two groups so far as the ultimate union of the maxilla was concerned. Only 3 in the entire group of 150 maxillae developed a degree of nonunion. On the other hand, when soft tissue wounds were left open for periods up to 1 or 2 weeks, a low grade surface infection developed which was attended by the gradual laying down of scar tissue and increasing disability. The author is of the opinion that disfigurement and deformity can be prevented to a great extent by meticulous primary débridement and layer repair as soon after injury as possible. There appears to be no sharp limit to the period in which primary repair can be successfully carried out. From this vantage point in the chain of the wounds which had been submitted to early and careful, albeit lengthy and tedious, layer repair were far ahead of those wounds which had been debrided and left open, requiring daily changes of soggy and malodorous dressings.

Upon arrival at this center the patient was carefully evaluated and pertinent laboratory data were procured. Indwelling nasogastric tubes were used when swallowing required painful effort. Continuous hot saline packs were applied to all areas exhibiting

any degree of swelling or sepsis. In all cases of wired teeth, spraying followed each feeding and the patient was encouraged to brush his teeth as often as possible.

Of the complications seen, maxillary sinusitis was the most frequent. It is virtually impossible to fracture the body of the maxilla without producing some degree of hemorrhage into the antrum. Eighty cases, or 53 per cent, showed some degree of sinusitis either clinically or roentgenologically, and 28 cases, or 18 per cent, required either a Caldwell-Luc operation or antral window construction rather urgently. This procedure was required 3 times as often in injuries not from missiles as in those caused by a projectile. This is probably associated with the production of an artificial nasal window by the missile, which gives ventilation and drainage to the antrum. Trismus occurred temporarily in nearly all of the face cases but was present as a late consideration in 17 cases, or 11 per cent, all but 2 of which had associated fractures of the mandible. Atresia of the nares occurred in 15 cases. Wound sepsis, chronic antraoral fistulas, malocclusion, and osteomyelitis were present in a small percentage of cases. Secondary hemorrhage did not occur. Nonunion of the maxilla resulted in 3 cases, or 2 per cent.

Of the 125 patients who were battle casualties, one-third returned to duty and two-thirds returned to the Zone of the Interior. Of the 25 civilians, two-thirds returned to duty and one-third went home.

FREDERICK W. MCKEYFIELD, M.D.

Barrera, G.: Osteomyelitis of the Jaws. Therapeutic Suggestions (Osteomielitis de maxilares. Conceptos sobre tratamientos). *Arch. soc. cir. hosp.*, 1945, 15: 754.

Osteomyelitis of the jaw may be of hematogenous origin and may follow scarlet fever, typhoid fever, or furuncles. In such cases the process is diffuse. A circumscribed lesion may follow a fracture or an infection of the teeth, usually of the lower molar teeth. A periapical osteitis may lead to the development of osteoperiostitis or osteomyelitis. Among the responsible bacteria the following must be mentioned: the aerobic and anaerobic streptococcus, the staphylococcus albus or aureus, and the pneumococcus. The spirillum combined with the fusiform bacillus is usually responsible for the characteristic fetor. The leptothrix buccalis and lactobacillus are found less frequently.

Among the signs and symptoms the following can be mentioned: pain in the involved area, tumefaction of the submaxillary suprahyoid regions and the lips, trismus caused by contracture of the levator muscles, hypesthesia of the skin of the chin, fever, tachycardia, pallor, and profuse perspiration.

As to the evolution, fistulas may form and, unless treated, they may create new abscesses. Extensive phlegmons may form at the base of the oral cavity or in the temporal fossa. Formation of a sequestrum may produce a pathological fracture.

Conservatism is advisable in the treatment of osteomyelitis of the jaw. Surgical procedures should

be confined to cases with circumscribed lesions in which it is possible to remove the sequestrum without interference with the teeth or alveolar processes. Fracture may be prevented by immobilization of the lower jaw, with the oral cavity occluded. In this manner a reparation of the bone and limitation of inflammatory processes in the soft parts can be facilitated. The parenteral use of penicillin is indicated in acute osteomyelitis of dental origin. In chronic osteomyelitis the usefulness of penicillin is more limited, but the drug is apt to diminish suppuration and facilitate drainage. After elimination of sequestra, the combined local use of sulfa drugs and penicillin suppresses postoperative drainage and produces spectacular curative effects. Inasmuch as it is difficult to predict whether an acute process of dental origin will terminate in the development of osteomyelitis, parenteral administration of from 800,000 to 1,000,000 units of penicillin is always advisable.

Since the introduction of modern chemotherapy, complications in the form of septicemia or septicopyemia are very rare. Quartz lamps greatly alleviate the symptoms caused by abscesses and phlegmons.

JOSEPH K. NARAT, M.D.

Jacoby, N. M., and Sagorin, L.: Osteomyelitis of the Jaws in Infancy. *Arch. Dis. Child.*, Lond., 1945, 20: 166.

Osteomyelitis of the maxilla is a rare condition, about 80 cases having been reported since 1847. It is practically confined to infants under the age of 12 weeks, whose previous history in relation to delivery and feeding is not significant. Usually, the condition has progressed for several days before it is recognized as being one of more than merely local inflammation. (In the present cases, this period averaged 8 days). The characteristic feature is gross swelling of the affected side. In the case of the maxilla, both eyelids are involved with proptosis and chemosis; the cheek is remarkably swollen and indurated. In addition there is frequently a unilateral purulent nasal discharge, and occasionally pus discharges externally from below the inner canthus of the eye. Inside the mouth the alveolus and the hard palate are swollen and inflamed, and the sinuses may be discharging either from the alveolus or the buccogingival fold; the buccogingival space may be markedly narrowed. When the mandible is involved, the swelling is mainly in the submental region, while inside the mouth, although the lower jaw is affected, the condition is essentially the same. From any of the purulent discharges, staphylococcus aureus can be cultured.

The etiology of this condition is not completely explained, since the portal of entry of the staphylococcus is unknown. A blood culture was taken in 1 of the cases reported by the authors, and a heavy growth of staphylococcus aureus was obtained within 24 hours. In the case of the maxilla, the bone infection is presumed to start in the tooth socket of the first molar.

The primary treatment in the first case was by operation on the maxilla, which in retrospect was far too radical, and without such interference there would probably have been a smaller loss of deciduous teeth. Subsequent experience showed that the best procedure is to rely mainly on penicillin and to carry out only such surgical measures as may be necessary to remove obvious collections of pus. Thus, while in case 1 an operation was performed first and penicillin was used afterwards, in the 2 subsequent cases penicillin was used from the very beginning and it was found that no surgery was required.

In case 2, in which the mandible was involved, a second prophylactic course of penicillin was given one week after termination of the first, as, in view of the recurrences reported in other cases of osteomyelitis, it was thought that a second course might help to prevent such a recurrence here. In the cases of maxillary involvement, the response to initial treatment was excellent and, considering the vascular nature of this bone in infancy, it was not thought necessary to repeat the penicillin.

In the past when treatment had consisted of free surgical drainage and, more recently, the addition of sulfonamides, the mortality in 43 cases reported in the literature was 31 per cent. In the present group of 3 cases there were no deaths, and although this series is too small to draw any definite conclusions, the fact that within 24 hours of starting treatment it was obvious that all 3 patients were going to recover and all danger had passed, would indicate that in the future the mortality rate will be low.

The cosmetic result (judging from photographs of published cases treated by surgical drainage) has not been perfect. There are usually one or more scars below the lower eyelid and these scars appear to be fixed to bone with resulting "pitting" of the area. In the first case in which pus was aspirated through the skin, scarring was minimal and there was no disfigurement. The subsequent cases had no scarring.

The loss of tooth buds is a further factor that should be mentioned, as it may lead to deformity and disfigurement when the teeth erupt later on. As the loss of tooth buds is due in part to surgical intervention, it is obvious that when penicillin is used and surgery is minimal, deformity due to the loss of teeth of the primary dentition will also be minimal.

Another point worthy of mention is the remarkable rapidity with which penicillin cures the disease. Thus, whereas the average duration of the surgically treated cases is about 3½ months, and even after this period some of them still had discharging sinuses, the 3 penicillin treated cases were cured and all sinuses healed in 12 days. ERNEST E. ARNHEIM, M.D.

EYE

Chamlin, M.: Oculomotor Paralysis with Partial Recovery; Report of a Case. *Arch. Ophthalm., Chic.*, 1946, 35: 23.

An opportunity was offered for the study of the action of various drugs in a case of unilateral internal

and external ophthalmoplegia, probably caused by a cerebral aneurysm. The action of cocaine, homatropine, pilocarpine, and physostigmine on the size of the parietic pupil, both during the stage of complete paralysis and the stage of partial recovery, was observed. Pilocarpine, which is believed to act as a cholinergic substance directly on the sphincter of the iris, caused contraction of the pupil, but physostigmine, which is thought to act by neutralizing the cholinesterase present at the myoneural junction, did not cause any pupillary contraction, probably because the defective third nerve was not producing sufficient acetylcholine to cause miosis. Similarly, cocaine dilated the pupil but homatropine did not.

It was noted that with partial recovery there was no pupillary response to light, but there had returned a normal response to physostigmine and homatropine which indicated that a stronger cholinergic tone is necessary for the light reflex than for response to the drugs. The patient exhibited the pseudo Grafe phenomenon, in which the lid is elevated on looking down.

WILLIAM A. MANN, M.D.

Wiser, H. J.: Eye Injuries in War Casualties Aboard a Hospital Ship. *U. S. Nav. M. Bull.*, 1946, 46: 67.

In 8 per cent of all casualties brought aboard ship, often directly from the beach heads, the eyelids, globe, and adnexa were injured. These injuries were usually associated with multiple wounds of the chest, abdomen, and central nervous system.

In spite of edema and chemosis, the fundus, muscles, and visual fields were examined routinely and roentgenographic plates were obtained. Foreign bodies (bullets, shell fragments, fragments of helmet, coral or lava) were found in practically all cases.

Burns were treated by irrigation, wet dressings, butyn, metaphen, and the instillation of penicillin (2,000 units per cubic centimeter) every 2 hours for a period of 72 hours. In only 2 per cent of flash burns of the eyelids was the cornea or conjunctiva involved.

A sulfonamide was dusted into the lacerated wounds before approximation with sutures; dirt particles were removed or excised to prevent tattooing. Extensive lacerations required plastic procedures.

Superficial lacerations were irrigated, 2 per cent butyn was instilled, and if iritis was suspected the pupil was dilated, and local and systemic penicillin therapy was instituted.

For perforations at the limbus, the prolapse was resected and the perforation covered with a sliding conjunctival flap; physostigmine salicylate was instilled, penicillin ointment introduced, and a pressure bandage applied.

Central perforations were treated by dilatation of the pupil and the application of a conjunctival flap.

For the removal of magnetic foreign bodies in the anterior chamber, a hand magnet was used through a keratome incision; nonmagnetic foreign bodies were removed with forceps. Penicillin and foreign protein therapy were administered in all cases of perforation of the eyeball.

any degree of swelling or sepsis. In all cases of wired teeth, spraying followed each feeding and the patient was encouraged to brush his teeth as often as possible.

Of the complications seen, maxillary sinusitis was the most frequent. It is virtually impossible to fracture the body of the maxilla without producing some degree of hemorrhage into the antrum. Eighty cases, or 53 per cent, showed some degree of sinusitis either clinically or roentgenologically, and 28 cases, or 18 per cent, required either a Caldwell-Luc operation or antral window construction rather urgently. This procedure was required 3 times as often in injuries not from missiles as in those caused by a projectile. This is probably associated with the production of an artificial nasal window by the missile, which gives ventilation and drainage to the antrum. Trismus occurred temporarily in nearly all of the face cases but was present as a late consideration in 17 cases, or 11 per cent, all but 2 of which had associated fractures of the mandible. Atresia of the nares occurred in 15 cases. Wound sepsis, chronic antraoral fistulas, malocclusion, and osteomyelitis were present in a small percentage of cases. Secondary hemorrhage did not occur. Nonunion of the maxilla resulted in 3 cases, or 2 per cent.

Of the 125 patients who were battle casualties, one-third returned to duty and two-thirds returned to the Zone of the Interior. Of the 25 civilians, two-thirds returned to duty and one-third went home.

FREDERICK W. MERRIFIELD, M.D.

Barrera, G.: Osteomyelitis of the Jaws. Therapeutic Suggestions (Osteomielitis de maxilares. Conceptos sobre tratamientos). Arch. soc. cir. hosp., 1945, 151: 784.

Osteomyelitis of the jaw may be of hematogenous origin and may follow scarlet fever, typhoid fever, or furuncles. In such cases the process is diffuse. A circumscribed lesion may follow a fracture or an infection of the teeth, usually of the lower molar teeth. A periapical osteitis may lead to the development of osteoperiostitis or osteomyelitis. Among the responsible bacteria the following must be mentioned: the aerobic and anaerobic streptococcus, the staphylococcus albus or aureus, and the pneumococcus. The spirillum combined with the fusiform bacillus is usually responsible for the characteristic fetor. The leptothrix buccalis and lactobacillus are found less frequently.

Among the signs and symptoms the following can be mentioned: pain in the involved area, tumefaction of the submaxillary suprahyoid regions and the lips, trismus caused by contracture of the levator muscles, hypesthesia of the skin of the chin, fever, tachycardia, pallor, and profuse perspiration.

As to the evolution, fistulas may form and, unless treated, they may create new abscesses. Extensive phlegmons may form at the base of the oral cavity or in the temporal fossa. Formation of a sequestrum may produce a pathological fracture.

Conservatism is advisable in the treatment of osteomyelitis of the jaw. Surgical procedures should

be confined to cases with circumscribed lesions in which it is possible to remove the sequestrum without interference with the teeth or alveolar processes. Fracture may be prevented by immobilization of the lower jaw, with the oral cavity occluded. In this manner a reparation of the bone and limitation of inflammatory processes in the soft parts can be facilitated. The parenteral use of penicillin is indicated in acute osteomyelitis of dental origin. In chronic osteomyelitis the usefulness of penicillin is more limited, but the drug is apt to diminish suppuration and facilitate drainage. After elimination of sequestra, the combined local use of sulfa drugs and penicillin suppresses postoperative drainage and produces spectacular curative effects. Inasmuch as it is difficult to predict whether an acute process of dental origin will terminate in the development of osteomyelitis, parenteral administration of from 800,000 to 1,000,000 units of penicillin is always advisable.

Since the introduction of modern chemotherapy, complications in the form of septicemia or septopyemia are very rare. Quartz lamps greatly alleviate the symptoms caused by abscesses and phlegmons.

Wiser, H. J.: Eye Injuries in War Casualties Aboard a Hospital Ship. *U. S. Nav. M. Bull.*, 1946, 45: 67.

In 8 per cent of all casualties brought aboard ship, often directly from the beach heads, the eyelids, globe, and adnexa were injured. These injuries were usually associated with multiple wounds of the chest, abdomen, and central nervous system. In spite of edema and chemosis, the fundus, muscles, and visual fields were examined routinely and roentgenographic plates were obtained. Foreign bodies (bullets, shell fragments, fragments of helmet, coral or lava) were found in practically all cases. Burns were treated by irrigation, wet dressings, (2,000 units per cubic centimeter) every 2 hours for a period of 72 hours. In only 2 per cent of flash burns of the eyelids was the cornea or conjunctiva involved. A sulfonamide was dusted into the involved wounds before approximation with sutures; dirt particles were removed or excised to prevent tattooing. Extensive lacerations required plastic procedures.

Superficial lacerations were irrigated, 2 per cent butyn was instilled, and if iritis was suspected the pupil was dilated, and local and systemic penicillin therapy was instituted.

For perforations at the limbus, the prolapse was resected and the perforation covered with a sliding conjunctival flap; physostigmine salicylate was instilled, penicillin ointment introduced, and a pressure bandage applied.

Central perforations were treated by dilatation of the pupil and the application of a conjunctival flap. For the removal of magnetic foreign bodies in the anterior chamber, a hand magnet was used through a keratome incision; nonmagnetic foreign bodies were removed with forceps. Penicillin and foreign protein therapy were administered in all cases of perforation of the eyeball.

Small metallic foreign bodies in the orbit were not removed unless an inflammatory reaction resulted; larger ones were removed to prevent future trouble.

In zygomatic fractures, depression of the infra-orbital ridge and floor of the orbit resulted in deformity unless the fragments were elevated within the first week. A pack in the maxillary sinus was used to hold the orbital ridge and floor in position.

In fractures of the supraorbital ridge with involvement of the frontal sinus, the bony fragments were replaced, a drain was sutured into place, and the soft tissues were approximated.

In nearly all cases of severe trauma to the orbital wall, the eyeball was ruptured or badly damaged.

Immersion blast injuries were few; atmospheric blast injuries were common. In blast injuries, hemorrhages in the vitreous, choroidal tears, and retinal hemorrhages were present.

Enucleation or evisceration was done without delay when indicated, especially to prevent sympathetic ophthalmia.

The results obtained with penicillin and sulfonamide therapy were very gratifying.

JOSHUA ZUCKERMAN, M.D.

Duke-Elder, P. M., and Wittkower, E.: Psychological Reactions in Soldiers to Loss of Vision of One Eye. *Brit. M. J.*, 1946, 1: 155.

One hundred and two soldiers with loss of vision of one eye were studied with regard to the duration of their disability, rank, type of enlistment, age, marital status, and attributability of injury to enemy action. The authors discuss the psychological reactions of these men to their disability. It was found that the type of emotional reaction to the loss of an eye is determined by: previous personality, minor or no emotional maladjustment, social anxiety over dependants, or self-centered, self-pitying anxiety, the nature of the disability, the nature of employment, and the retention of a blind eye.

The authors conclude that because the psychological effect of the loss of an eye is out of proportion to the actual physical disability, treatment is by no means completed with only medical attention to the eye. They believe that measures should be taken not only to improve the occupational prospects of the patient, but also to impress their employers with the fact that in most vocations the loss of one eye results in only a negligible loss of efficiency.

JOSHUA ZUCKERMAN, M.D.

Schele, H. G., and Hodes, P. J.: Injection of Oxygen into Tenon's Capsule. *Arch. Ophthalmol.*, Chic., 1946, 35: 13.

The authors discuss the injection of contrast mediums into Tenon's capsule for radiographic differentiation of intraocular foreign bodies from those outside the eyeball. The method is also useful for localizing foreign bodies near the limits of the eyeball and for diagnosing double perforations of the eyeball. They recommend the use of oxygen by injection into Tenon's capsule.

The injection of air with resultant external pressure made immediate surgical intervention hazardous (danger of loss of vitreous, and prolapse of the iris), especially when the anterior chamber had to be opened for removal of a foreign body by the anterior route, or for linear extraction of a traumatic cataract. The injection of carbon dioxide was also tried. It was found that air is not absorbed completely for from 3 to 4 days; carbon dioxide is absorbed too rapidly to be effective as a contrast medium.

Oxygen proved to be ideal for visualization of the eyeball. It was absorbed slowly enough to permit re-examination, yet quickly enough to avoid the risk of escape of vitreous at operation. Most of the oxygen is absorbed within 4 to 8 hours.

The technique described by Spackman is recommended. With a curved 25 gauge needle (attached to a 10 c.c. syringe), inserted from 5 to 6 mm. behind the limbus in the upper outer quadrant of the eye, 6 c.c. of oxygen are introduced slowly to produce proptosis.

JOSHUA ZUCKERMAN, M.D.

Town, A. E., and Hunt, M. E.: Penicillin in the Aqueous Humor. *Am. J. Ophthalmol.*, 1946, 29: 171.

Experimental investigation of penicillin concentration in the blood and aqueous of rabbits and monkeys following intramuscular injections was undertaken, using the Rammelkamp method of assay. Aqueous was withdrawn with a fine hypodermic needle and forty minutes later the secondary aqueous obtained. In all cases the penicillin content of the aqueous was found to be very low in relation to the blood level but the secondary aqueous showed nearly as great a concentration of penicillin as the blood.

Clinically the experimental work indicates that massive doses of penicillin are required to produce any effective concentration in the aqueous.

WILLIAM A. MANN, M.D.

Reese, A. B., and Payne, F.: Persistence and Hyperplasia of the Primary Vitreous (Tunica Vasculosa Lenticis or Retrolental Fibroplasia). *Am. J. Ophthalmol.*, 1946, 29: 1.

The condition reported by the authors is manifested as a bilateral congenital lesion in premature infants. The basic lesion is a persistence, in part or in toto, of the primary vitreous, with or without hyperplasia and with or without secondary changes consequent to hemorrhage, opening of the lens capsule, and glaucoma.

As a result of the lowered mortality of premature infants in the past decade, lesions of this type are encountered more frequently now. Clinically, there are 4 types, which may coexist or merge:

1. The typical and most frequent manifestation is a saucer-shaped, whitish opaque tissue conforming to the posterior surface of the lens.
2. An opaque cornea, greatest centrally, and usually associated with glaucoma.
3. A localized area of opaque tissue on the posterior surface of the lens at the equator of the lens.

or in the anterior vitreous, with or without retinal detachment.

4. Remains of the hyaloid system.

For the associated glaucoma, the authors have tried iridencleisis, cyclodialysis, trephining, and iridectomy with sclerectomy, but iridencleisis appears to be the treatment that is most effective. The lens substance can be removed by repeated extensive dissection, and finally by a central vertical cut in the retrolental fibrous tissue with deWecker's scissors.

The authors state that the lesion appears to be related to hemangioma of the skin of the face, the scalp, the body, or the extremities.

JOSHUA ZUCKERMAN, M.D.

Rados, A.: The Occurrence of Glioma of the Retina and of the Brain in Collateral Lines in the Same Family; Genetics of Glioma. *Arch. Ophthalm.*, Chic., 1946, 35: 1.

The occurrence of glioma of the retina and of the brain in collateral lines of the same family is discussed. The author points out that heredity depends on the intrinsic factors, the genes, and extrachromosomal influences. In malignant tumors, with the exception of gliomas and neurofibromatosis, heredity is of minor importance. Gliomas are relatively rare.

Elschnig reported a case of unilateral glioma in a girl 2 years of age, whose 13 year old sister died 10 years later of infiltrative glioma of the large hemisphere of the brain.

In the present article, the author reports the occurrence of malignant growths of the same type in the retina and in the brain, in collateral lines of the same family—1 case of glioma of the retina, and 1 of glioma of the brain. The females themselves, who were not affected, were the transmitters to a male and to a female child, respectively.

In conclusion, the author states that retinoblastomas have a hereditary basis and that apparently they originate from lesions which are intermediate between developmental disturbances and true neoplasms.

JOSHUA ZUCKERMAN, M.D.

EAR

Hipskind, M. M.: War Injuries to the Auditory Apparatus. *Laryngoscope*, 1945, 55: 678.

The records show that 5.8 per cent of all patients admitted to the One Hundred and Eighth General Hospital suffered from acoustic trauma. The author reviews 790 case records of soldiers who complained of impaired hearing caused by explosion, and presents the following summary and conclusions.

Combatant personnel exposed to the effects of battle noises have demonstrated a tonal dip maximal at 4,096 cycles when tested in a soundproofed room with a standardized audiometer.

Ear injury incurred in combat, as manifested by a tonal dip, could be recognized before the speech frequency range was affected. The application of this knowledge proved to be a satisfactory basis for the classification and ultimate disposition of soldiers.

Ears with hearing impairment existing prior to military service proved to be as vulnerable as normal ears, when exposed to the noise of combat.

No correlation was found between the degree of objective eardrum injuries and the degree of hearing impairment.

Aural battle casualties presented a paucity of complaints referable to the receptors for equilibrium and, more rarely, diplacusis. Deafness was commonly associated with tinnitus. In those patients complaining of tinnitus only, the maximum threshold elevation was at 11,584 cycles.

A method of detection of malingers was developed.

Temporary deafness of the left ear, caused by the muzzle-blast from the soldier's own rifle, appeared to predispose to combat injuries from explosions occurring in the area of the soldier's left side.

Hysterical and simulated deafness was not uncommon. These two types of deafness responded well to proper identification and treatment.

No evidence was found that would indicate a "cumulative factor" in acoustic trauma.

JOHN F. DELPE, M.D.

Otte, J.: Labyrinthitis (Labyrinthitis). *Rev. otorr.*, 1945, 5: 216.

Labyrinthitis is a relatively frequent complication of suppuration of the ear occurring in approximately 1.5 per cent of the cases of otitis media. The propagation of infection may follow various paths such as fenestrum ovale, vestibulum, semicircular canals, or the promontory canal of the facial nerve. Rarely, perforation of the eustachian tube may occur.

A circumscribed and a diffuse form of labyrinthitis may be distinguished. If the infection spreads slowly, inflammatory adhesions prevent a further propagation of the infection and a labyrinthian fistula forms. Endosteum is extraordinarily resistant to infections, and because of its excellent vascularization it reacts intensely to an invasion by microorganisms. All such circumstances explain the relatively great frequency of fistulas. A circumscribed labyrinthitis may follow a slow extension of the infection responsible for a chronic otitis media, especially cholesteatoma, while an acute otitis media leads more frequently to a diffuse labyrinthian process.

The author recommends Kopetzky's classification of clinical forms.

Profound modifications in the evolution of labyrinthitis are provoked by penicillin and the sulfa drugs.

The author describes a case of labyrinthitis in which an erosion of the external semicircular canal was found. This focus was eliminated without paying attention to the danger of meningeal propagation.

In a case of perilabyrinthitis no labyrinthian lesion could be found on inspection, but the vestibular apparatus was destroyed with the purpose of putting an end to the dizzy spells. No postoperative complications developed.

The author describes a case of suppurative otitis media complicated by a diffuse serous labyrinthitis and purulent meningitis. The patient was cured with penicillin without surgical intervention. The author believes that since the introduction of new therapeutic methods, especially the use of penicillin, the indications for surgical intervention in labyrinthitis have become more limited. JOSEPH K. NARAT, M.D.

Letellier, R. V.: Petrositis (Petrositis). *Rev. otorr.*, 1945, 5: 256.

The author reports 4 cases of petrositis. Especially interesting was the case in which a wrong diagnosis had been made: a boy presented a clinical picture of petrositis following a mastoid operation and roentgenograms in Stenvers position revealed an osseous lesion. However, no pathological changes of the petrous bone were found at the operation performed according to Lempert's rules. The autopsy revealed tuberculous meningitis.

The main micro-organism responsible for petrositis is the hemolytic streptococcus. The infection usually spreads across the anterosuperior portion of the promontory and the peritubal zone. Following a mastoid operation, otorrhea and earache persist and the pain radiates toward the periorbital and occipital regions. A paralysis of the facial nerve may develop if the infection involves the anterosuperior portion of the promontory. Diplopia is frequent. Deafness, dizziness, vomiting, and nystagmus may occur when the process is accompanied by a labyrinthian irritation. Gradenigo's syndrome is not typical of petrositis because it may also appear in the course of mastoiditis, meningitis, or thrombophlebitis of the lateral sinus. A gradual disappearance of suppuration and attenuation of the pains are good prognostic signs, while a sudden cessation of otorrhea and the pains should be looked upon with suspicion. A latent period has been observed by the author in 1 of his cases.

Among the general symptoms, asthenia, loss of appetite, and subfebrile temperature may be mentioned. A paralysis of the external branch of the oculomotor nerve seems to occur in more than half of all the cases. Unless there are complications in the brain or meninges the findings in the spinal fluid are negative. Blood examination usually shows a slight leucocytosis. Roentgenography is of considerable value although the interpretation of the findings may be difficult and the otologist must rely chiefly on the clinical picture.

Asymptomatic petrositis has been described. Among the most frequent complications, meningitis and septicemia must be mentioned.

The differential diagnosis should consider osteomyelitis of the petrous bone, thrombophlebitis of the lateral sinus, labyrinthitis, and tuberculous meningitis. As to the clinical forms, the following types may be distinguished according to the location of the infection: basal and apical petrositis, and panpetrositis. Congestive and suppurative forms may be distinguished.

As to the evolution of the process, a spontaneous recovery may occur, or the condition may become chronic. Spontaneous perforations may develop and reach the contents of the skull, the pharynx, or the carotid canal.

Chemotherapy apparently does not prevent the spread of the infection and therefore surgery is unavoidable. The author has been using Lempert's operation with great success. If patients who have undergone a mastoid operation complain of periorbital pain, a careful search for fistulous tracts at the base of the petrous bone is indicated. Unless the process is located at the apex of the petrous bone, a complete petromastoid operation will cure the petrositis. JOSEPH K. NARAT, M.D.

Smith, A. T.: Clinical Use of Penicillin in Infections of the Ears, Nose, and Throat. *Arch. Otol.*, Chic., 1946, 43: 12.

The author reviews his experience with the use of penicillin in the treatment of ear, nose, and throat infections at the U. S. Naval Hospital, Portsmouth, Virginia, since 1943.

There was no response to penicillin in the cases of patients with chronic suppurative otitis media; however, in acute suppurative otitis media, which was due to penicillin sensitive organisms in nearly all cases, the response to systemic treatment was prompt and often dramatic.

In cases of mastoiditis with complications requiring mastoidectomy, penicillin played an important part in recovery, and in the rapid healing of wounds.

Acute multiple sinusitis responded favorably to systemic therapy, and surgical work was greatly reduced. It was difficult to determine the value of local therapy in maxillary sinusitis. The general impression was that a combination of systemic and local treatment was better than the use of either method alone. In chronic sinusitis with mixed infections, it was not clear that penicillin was an aid to the usual local treatments and operative procedures.

Penicillin was valuable in the treatment of acute follicular tonsillitis, but was not of value in the treatment of rheumatic fever and infectious mononucleosis. It was of value, however, in the treatment of Ludwig's angina and cellulitis, and in adenitis complicating dental surgery. In cases of osteomyelitis of the mandible, surgical treatment also was necessary. JOHN R. LINDSAY, M.D.

NOSE AND SINUSES

Callomon, F. T., and Linton, L. G.: Tissue Changes Produced in the Nasal Mucous Membrane of Normal Mice by Prolonged Local Administration of Some Solutions Containing Sulfonamide Compounds. *Arch. Otol.*, Chic., 1946, 43: 31.

The authors carried out a series of experiments on mice, to determine the histological changes occurring in the nasal mucous membrane as a result of the prolonged local administration of several solutions

containing sulfonamide compounds. The solutions were dropped into the nose twice daily and the animals were killed at various periods. A 3 per cent solution of propylene glycol alone (pH 5.4) had no detrimental effect on the mucosa, nor did an isotonic solution of sodium chloride produce a detrimental effect. Three per cent sulfathiazole in propylene glycol (pH 5.1) produced only a slight inflammatory reaction. Two per cent diasein in propylene glycol (pH 4.8) caused considerable inflammation of the mucous membrane with moderate alteration of the olfactory layer. These changes increased when treatment was prolonged. The addition of 10 per cent sodium bicarbonate to 3 per cent diasein in propylene glycol (pH 8.8) produced increasing inflammatory reaction. Other preparations of diasein, succinyl sulfapyrazine, and a commercial preparation containing desoxyephedrine and sodium sulfathiazole in aqueous solution (pH 9.2) showed similar marked inflammatory reaction in the mucosa, followed by a slow return to normal after the treatment was ended. The 2 per cent diasein solution with a pH below 5 caused much greater damage than the alkaline solution with pH 8.8.

Wolf, G. D.: Colloidal Nasal Tamponades. *J. Am. M. Ass.*, 1946, 130: 273.

The use of nasal tamponades saturated with a solution of mild protein silver in nasal therapeutics is discussed.

Although this method of therapy has been widely used, there is no unanimity of opinion as to its value, recognized authorities expressing divergent opinions. Direct scientific proof of its value has not been demonstrated.

The effectiveness of colloidal silver is said to be due to its immediate irritant properties, resulting in stimulation of the flow of mucus, and a subsequent mild antiseptic effect which is in proportion to its free silver ions. The strong protein silver group, according to "New and Nonofficial Remedies," is most effective, but is slightly irritant and stimulant, while the mild silver protein salts (U.S.P.) act largely as a demulcent and a detergent through the dislodging of pus.

Physiologic studies show that the nasal and sinus mucosa is covered by a thin film of mucus which is swept along by ciliary action to the nasopharynx and eventually reaches the pharynx and stomach. This provides a natural defense for the upper respiratory tract against infection. Ciliary action is not necessarily aided by the use of antiseptics.

While scientific evidence suggests that colloidal silver has no value in nasal therapeutics, the author has found the use of nasal "packs" to be of value in a selected clinical group.

They were of no value in purulent sinusitis, or in the presence of physical obstruction, such as deflected septum, hypertrophied turbinates, and polypi, or in allergic patients. A group of patients, usually plethoric in type, was found, however, who complained

of vague headaches, nasal stuffiness, and discharge, and who experienced marked relief after treatment with 10 per cent colloidal silver solution on packs.

Prolonged use of nasal tampons for treatment of chronic sinusitis has no place in nasal therapy.

MOUTH

Waldron, C. W., Peterson, R. G., and Waldron, C. A.: Surgical Treatment of Mandibular Prognathism. *J. Oral Surg.*, 1946, 4: 61.

In approaching the problem of mandibular prognathism, a careful and thorough diagnostic study of the individual case is essential. The history should include any deformities in parents or other members of the family, and the presence of nasopharyngeal obstruction in the patient, which may have caused voluntary protrusion of the lower jaw in an effort to secure an adequate airway. Photographs, x-rays of the jaws, dental examinations, and duplicate impressions and casts of the upper and lower teeth with bite recordings should be made.

By matching the lower cast with the upper cast, a preliminary estimation of the occlusal relationship after surgical replacement is usually possible. It can then be determined whether orthodontic treatment of the upper or lower teeth of both arches is indicated before or after surgical repositioning. Also, a careful study of the casts may indicate whether excising sections of the body of the mandible or osteotomy of the ramus is the operation of choice. To facilitate in this planning, a special mount or articulator for the casts is used (Fig. 1).

The operative method employed is selected according to the needs of the individual case. In many the desired correction may be obtained by excision of a section of the body of the mandible in the retromolar region, either unilaterally or bilaterally. The predetermined length of bone is removed under direct vision through a submandibular approach, preserving the alveolar nerve if possible, and the bone ends are fixed in approximation with silver wire. Immobilization of the jaws is maintained by interdental wiring for a period of 8 weeks.

In some cases examination of the casts will indicate that occlusion would be better established by means of diagonal osteotomy and resection of a previously estimated amount of bone from the ramus just above the angle of the mandible, or by horizontal division of the ramus and wiring of the fragments after setting back the lower fragment the desired distance. Approach to the ramus is made through an incision placed 1 cm. behind and slightly below the attachment of the lobe of the ear, and extending downward for a distance of $1\frac{1}{4}$ inches in a line parallel with the posterior border of the ramus. The parotid fascia and gland are bluntly dissected to expose the periosteum along the posterior margin of the ramus. Transverse sectioning of the ramus is made no lower than $\frac{1}{2}$ inch below the mandibular notch in order to avoid injury to the inferior alveolar

Fig. 1. Diagrammatic plan of the articulator we are using for preoperative study of the procedure to be carried out. Measurements in the vertical plane from A to A', B to B', C to C', are checked on the repositioned cast to determine the elevation or depression of the anterior or

posterior teeth indicated to obtain the best possible occlusion. By these determinations, an estimate may be made of the necessity of a diagonal section of the ramus rather than section through the horizontal plane.

vessels and nerve. Fixation is attained by wiring of the fragments and by intraoral wiring. In edentulous patients it may be necessary to resort to some form of external fixation. In special instances, such as coexistent cleft palate deformities, the operative correction of the mandibular deformity is planned in conjunction with dental or prosthetic work on the maxilla.

In the authors' series there was usually seepage of parotid fluid from the incisions, lasting from 3 or 4 days to as long as 23 days. In a few cases partial facial paralysis developed, in no case occurring bilaterally, or persisting permanently. These disadvantages, however, are considered less troublesome than those encountered when an intraoral approach is used, since better visualization of the operative field is attained and the wounds are not contaminated by the oral cavity. Local anesthesia is preferred because of the hazards of vomiting after general anesthesia when the jaws are wired.

The improvement attained in facial appearance, function of mastication, and mental attitude of the patients in a series of some 50 cases has been most gratifying.

JOSEPH J. McDONALD, M.D.

This period, no attempt was made to give the patient fluids by mouth, feeding being entirely by the intravenous route. A nasal feeding tube was inserted as soon as the patient's condition allowed. A high protein liquid feeding every hour proved satisfactory. Penicillin, 20,000 units every 3 hours, was given routinely.

The course of a bullet as determined by the point of entrance and exit did not indicate that the damage caused was limited to its path. The transmitted explosive force in passing through the tissues caused serious remote damage in many instances. X-rays and fluoroscopic examination were often of great assistance in locating and removing foreign bodies.

Perforation of the esophagus should be suspected in all cases in which the larynx or trachea has been injured. Restricting fluids by mouth and feeding by tube is a good policy for all patients in whom any damage to the esophagus is suspected. Damage to the large vessels of the neck must be suspected no matter how small the point of entrance of the foreign body.

It is emphasized that obvious facial injuries may be associated with cord damage, injury to the larynx, trachea, pharynx, esophagus, or large vessels of the head and neck. It is well established also that every severe facial fracture should be considered a basal skull fracture until proved otherwise.

The treatment of facial wounds follows the accepted pattern of treatment of all war wounds. Light closure without drainage should never be done. It was necessary to remove sutures and establish drainage on practically every case which had been closed in this manner before the patient was received aboard ship. Approximation of the wound with drainage after careful cleansing and conservative débridement was done as soon as possible. Whenever possible, a

Wiser, H. J., and McAfee, M. F.: Injuries of the Face and Neck in War Casualties. *U. S. Nav. M. Bull.*, 1946, 46: 57.

This is a report of neck and face injuries treated aboard a hospital ship. The urgent problems encountered in injuries of the head and neck are shock, hemorrhage, and respiratory distress. Any work which did not come under the urgent classification was postponed until the patient had been thoroughly examined and his condition evaluated. At the end of 24 or 48 hours the patient was invariably in much better condition for anesthesia and surgery. During

pressure dressing was applied. Dirt, powder marks, or other pigmented material required careful removal from facial wounds. The use of a stiff scrub brush and soap are frequently necessary.

It is often possible, by early repair of facial wounds, to shorten a patient's hospitalization by many months. In a high percentage of cases of soft tissue wounds of the face, there was associated trauma to the bony structures. Practically all fractures were compound and comminuted. There was always a considerable amount of shock in this type of injury. Dyspnea was often present and caused the patient much discomfort and apprehension. Tracheotomy was frequently performed in these individuals. In severe injuries it is not considered advisable to attempt fixation of the jaw fragments, elevate the malar bones, or attempt reduction of the nasal bones until the condition of the patient has stabilized, usually after from 48 to 72 hours. Early manipulation adds to the shock of the patient, excites hemorrhage, and increases the danger of meningitis. Arch bars with rubber band traction were used for the reduction and fixation of fractures of the maxilla and mandible.

It can be readily seen that no rule can be set down to govern early treatment of all types of facial fractures encountered in war casualties. In the event of rhinorrhea a minimum amount of manipulation was done. Both penicillin and sulfadiazine were given in all cases in which there was believed to be imminent danger of meningitis.

FREDERICK W. MERRIFIELD, M.D.

Director of the Institute of Radium: Cancer of the Oral Cavity; Its Location and Frequency.
(Cánceres de la cavidad bucal, localización y frecuencia). *Arch. cub. canc.*, 1945, 4: 238.

During the period from 1924 to 1944, 1,329 patients with cancer of the oral cavity had been treated at the Radium Institute in Cuba. The cases were distributed as follows: lips (486 patients), tongue (317), palate (206), tonsils (159), gums (72), base of the mouth (47), and cheeks (42). Cancer of the palate, tonsils, and base of the tongue was responsible for 33 per cent of all cancers of the oral cavity. On the lips the cancer was more frequently located in the center than on the sides. Cancer of the lips was encountered in 37 per cent of the total material.

The upper aspect of the tongue was affected much more frequently than the lower, and the base of the tongue was involved in a much greater number of cases than any other part of the organ. Cancer on the lower aspect of the lips was rare.

Of 206 cancers involving the palate, 152 were found on the soft palate or the pillars, and 54 on the hard palate. The uvula was involved in 44 instances. As to the tonsils, in many cases it was impossible to determine whether one was dealing with a primary carcinoma or a tumor spreading from the pillars or the pharyngeal wall.

The upper gums were the site of cancer twice as often as the lower gums. The middle third of the inner side of the cheeks was invaded by cancer more frequently than any other portion.

JOSEPH K. NARAT, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Morrison, L. R.: Histopathological Effect of Anoxia on the Central Nervous System. *Arch. Neur. Psychiat.*, Chic., 1946, 55, 1.

Damage to the nervous system as a consequence of anoxia has been produced in many ways, but most of the investigations dealing with this subject have borne but slight relation to the problem of aviation. The purpose of the present investigation was to determine whether histopathological alterations were produced in the central nervous system after repeated, sublethal exposures to an atmosphere deficient in oxygen; to measure the amount of oxygen to which the nervous system was exposed; and to correlate that amount, if possible, with the nature of the histopathological process. The extensive use of high-flying airplanes in war, with its accompanying hazards of failure of the oxygen supply, jumps from high altitudes, and the possible cumulative effect of the chronic day by day exposures to fatigue and anoxia, makes the need for such an investigation imperative.

The different conditions under which anoxia of the nervous system has been produced may be grouped under the classification of anoxias as suggested by Barcroft, or by Peters and Van Slyke: (1). anoxic anoxia is characterized by low oxygen tension of the arterial blood, so that the hemoglobin does not have its normal degree of oxygen saturation; (2). anemic anoxia is a condition in which insufficient amounts of hemoglobin are available for oxygen transport even though the oxygen tension is normal; (3). stagnant anoxia is the result of defective circulation of the blood during which the tissues fail to receive an adequate supply of oxygen even though the arterial blood contains sufficient oxygen in the proper degree of saturation; (4). histotoxic anoxia occurs when the tissue cells themselves are unable to utilize oxygen even though it is available in the arterial blood.

The authors then describe the materials and methods used in making their experiments, and review the pathological examination of 25 dogs and 10 monkeys subjected to varying types of anoxia. The brains of these animals were studied both grossly and microscopically, and the report includes a great number of photomicrographs showing the changes of the cell structures in different portions of the brain.

A summary of the findings may be given as follows:

Twenty-five dogs were exposed daily to atmospheres of low oxygen concentration at the pressure of sea level, and 10 monkeys were similarly exposed in a decompression chamber. The oxygen content of the arterial blood was measured in the dogs. Histological studies were made of the central nervous system of all of the animals and of the adrenal glands of the dogs.

It was found that a single, sudden exposure to a simulated altitude of 32,000 feet (10,000 meters) for 25 minutes was capable of producing extensive laminar necrosis in the cortex of the monkey.

With repeated exposures to mild hypoxia, it was observed that the first histological changes occurred in the cell bodies of the cortical gray matter. They took place at a level of about 12 or 13 volumes per cent of oxygen in the blood if the exposures were long enough and were repeated often enough.

When the percentage of oxygen was reduced still lower, to about 10 volumes per cent, and the number of exposures was increased, the white matter also became involved and presented a pattern of demyelination in the corpus callosum, the centrum semiovale, and the adjacent fingers of subcortical white matter which, in the cases of more severe anoxia, suggested a resemblance to Schilder's disease.

Aside from the lesion of the white matter, frank necrosis was usually found to occur, but only after episodes of anoxia sufficiently severe to produce the cessation of respiration.

The frontal lobe was most often involved and the temporal lobe least often. The cerebellum was more frequently affected than the basal ganglia, and the spinal cord and medulla were unaffected by any degree of anoxia compatible with life. An oxygen level of 4 or 4.5 volumes per cent was about as low as a dog could tolerate. Respirations quickly ceased below that level. The adrenal glands showed increased cortical activity. PAUL MENRELL, M.D.

Wilson, H. M., and Lutz, W. G.: Lesions of the Aqueduct of Sylvius. *Radiology*, 1946, 46: 132.

The first case of congenital occlusion of the aqueduct of Sylvius was reported by Hilton in 1847. Pancoast, Pendergrass, and Schaeffer have stated in their classic work, "The Head and Neck in Roentgen Diagnosis", that of all of the lesions revealed by ventriculography, those obstructing the aqueduct are the most difficult to diagnose. Twining emphasized the danger of being misled by inadequate visualization of the aqueduct and fourth ventricle and discussed the hydrodynamics involved in filling these structures with air.

Complete replacement of the cerebrospinal fluid with air is seldom possible by ventricular puncture in the presence of a blocked ventricular system. The difficulties encountered are largely technical and involve positional occlusion of the system. The roentgen diagnosis is dependent upon failure to visualize the aqueduct, together with the positive findings of obstructive hydrocephalus: namely, (1) symmetrical dilatation of the lateral ventricles; (2) dilatation of the foramina of Monro; (3) dilatation of the third ventricle; and (4) dilatation of the aqueduct rostral to the point of obstruction. These criteria may be established by conventional posi-

tioning in most cases in which an adequate replacement of fluid by air is effected by the neurosurgeon. In some cases, however, the superimposed bony structures of the cranium, or air in dilated lateral ventricles may obscure the region of the aqueduct, which necessitates the use of body section roentgenography. Midline lateral laminagraphs will give clear visualization of the aqueduct and the third and fourth ventricles in such cases. In all instances of failure to visualize the aqueduct or the fourth ventricle by conventional roentgenography, laminagraphs in both the lateral and frontal projections are taken.

The authors discuss the use of heavy opaque media and state that they are not regarded favorably. Definite localization of the site of obstruction in obstructive hydrocephalus is of paramount importance. A surgical decision to explore the lesion above or below the tentorium may rest largely upon ventriculographic findings. In reviewing their ventriculographic studies in cases of obstructive hydrocephalus, it was noted that rotation of the third ventricle on its horizontal axis occurred in a number of instances of subtentorial tumor. In order to evaluate the significance of this finding a group of cases of obstructive hydrocephalus was restudied. A line was drawn along the base of the anterior fossa and a second line was drawn from the anterior clinoid process to the suprapineal recess. The measured angle included between these lines was noted in two groups of proved supratentorial and infratentorial tumors, respectively, and in a control group of normal pneumoencephalograms. It was found that the angle was usually 140 degrees in normal air studies; it was significantly decreased in cases of infratentorial tumors, and was usually increased in non-neoplastic obstruction of the aqueduct above the tentorium.

The authors report 11 cases of neoplastic stenosis and 3 cases of non-neoplastic stenosis. The theories of both geneses of non-neoplastic stenosis are reviewed. The role of nutritional deficiency as an etiological factor is discussed in line with recent experimental evidence.

PAUL MERRELL, M.D.

Walter, W. G., and Dovey, V. J.: Delimitation of Subcortical Tumors by Direct Electrography. *Lancet*, Lond., 1946, 250: 5.

It is not surprising to see that elaborations and additions to the recent science of electroencephalography are already beginning to appear. The authors have created a device for direct measurement of electrical potentials of the brain, "electrography," which consists of an insulated electrode which is passed into the brain at operation much as any ordinary ventricular canula would be manipulated, in the effort to locate subcortical lesions by the change from normal to abnormal brain wave patterns. A graph is obtained in very much the same way as in ordinary electroencephalography. Several case histories are recorded to demonstrate the usefulness of this little machine.

The greater immediate possibility of the procedure is the fact that it offers a method for the more thorough physiological exploration of the normal intact brain and its electrical activity in the various regions of a subcortical location less accessible to indirect electroencephalography. As the authors have pointed out, it may aid in the explanation of some of the incompletely understood phenomena of indirect electroencephalography.

JOHN MARTIN, M.D.

Freeman, W., and Watts, J. W.: Prefrontal Lobotomy. A Survey of 331 Cases. *Am. J. M. Sc.*, 1946, 211: 1.

The surgical treatment of certain types of mental disturbances is possible because of the demonstration that patients may survive and be apparently well despite the loss of a considerable portion of their prefrontal lobes. Its success rests upon the theoretical consideration that it interrupts long established synaptic pathways which have resulted in unsatisfactory emotional behavior. Results in the "best" cases show very little impairment of intelligence as measured by tests employed, and further inquiry into the functions of the prefrontal lobes was stimulated. Fundamentally, it is believed that the frontal lobes subserve the functions of foresight and insight, particularly as related to the self.

The authors conceive the psychosis in the terms of Egas Moniz; namely, the pathological stabilization of synaptic patterns among various cell groups, particularly in the frontal lobes. With the development of fixation of the psychosis, they suggest that there occurs, through the process of facilitation, the inclusion of a progressively larger number of cortical cell population into the pattern of behavior. They believe that the spread of the psychosis is in a posterior direction. At the present time they are inclined to the working hypothesis that the results of the operation depend upon the number of fibers severed in the anterior thalamic peduncle, and they endeavor to place the incisions so as to strike the proper balance between the abolition of the disalting psychosis and the preservation of the capacity for productive work. The more severe the psychosis and the longer it has been established, the farther back, and deeper, they make the incisions. The operative procedure for prefrontal lobotomy is briefly described.

Of the 331 cases subjected to this procedure, the authors report the results as follows:

Good, 52 per cent; fair, 32 per cent; poor, 13 per cent; and deaths, 3 per cent. Of the 266 living patients in June, 1945, who have survived from 6 months to 9 years, 30 are regularly employed, 8 are partly employed, 22 are keeping house, and 17 are in hospitals. The authors emphasize that the procedure should not be performed except in those cases in which more conservative procedures have failed, but that it should not be delayed until too much deterioration has occurred. The most favorable results have been obtained in obsessive tension states,

with or without compulsions, in hypochondriasis, intractable psychosomatic conditions, and in agitated depressions. Less satisfactory results are obtained in schizophrenias, although as long as the patient is fighting his disease there still remains the possibility of satisfactory modification of his behavior. Alcoholism, paranoid states, and psychoses with organic brain diseases yield rather poor results.

JOHN W. ERTON, M.D.

Turner, E. K.: Purulent Meningitis of Infancy and Childhood; A 12 Months' Survey of the Results of Treatment with Penicillin. *Med. J. Australia*, 1946, 1: 14.

The author summarizes her methods of treating purulent meningitis and the clinical results obtained in a series of 54 bacteriologically confirmed cases. There were 29 cases of meningococcal meningitis, 15 of pneumococcal meningitis, 7 of streptococcus hemolyticus meningitis, and 3 of staphylococcus aureus meningitis. The ages of the children ranged from 6 weeks to 12 years, the largest number being under 6 years of age.

The cases were divided into 2 groups on the basis of the acuteness and severity of the meningitis. When the clinical findings indicated a subacute form of the disease, the patients were treated entirely with the sulfonamide drugs unless an unsatisfactory clinical response necessitated the supplementary use or substitution of penicillin.

Sixteen patients treated only with sulfonamides recovered.

When the history and clinical findings indicated the presence of a hyperacute or fulminating meningococcal meningitis either with or without meningococcemia, the intrathecal administration of penicillin was employed. In this second group were also included those cases of pneumococcal, streptococcal, and staphylococcal meningitides. An initial dose of from 10 to 20,000 units of penicillin was administered by the intrathecal route upon establishment of the diagnosis and repeated once daily for an average of 4 days.

Penicillin was administered both intravenously and intramuscularly to control the meningococcemia. In addition, sulfonamides were given by mouth. Fourteen fulminant patients with meningococcal meningitis so treated recovered. Fifteen with pneumococcal meningitis were treated by the combination of intrathecal penicillin and oral sulfonamides, 8 recovered and 7 died. Of 7 with streptococcus hemolyticus meningitis so treated, 2 recovered and 5 died, and all 3 patients with staphylococcus aureus meningitis recovered.

The author believes that cases of fulminating meningococcal meningitis and other purulent types of meningitis demand the intrathecal administration of penicillin. It should be combined with oral administration of the sulfonamides. No toxic effects were observed in this series following the instillation of penicillin in the spinal cord.

LAURENCE M. WEINBERGER, M.D.

SPINAL CORD AND ITS COVERINGS

Ver Bruggen, A.: Extradural Spinal Hemorrhage. *Ann. Surg.*, 1946, 123: 154.

Very rarely a case of spinal cord injury is seen in which the onset of paraplegia is gradual over a period of a few hours. When the paraplegia is complete, a sensory level is also distinct. Operation at the site suggested by the level and the paraplegia may disclose a localized extradural spinal hemorrhage, the removal of which may lead to complete recovery. Although the author has been aware during the last 15 years that the possibility of such a case existed, he had never encountered one and on consulting the literature there was very little evidence that such a case had been encountered by anyone else except as a rarity.

The case was that of a 75 year old, white male with an old Marie-Struempell's disease of the spine, who fell on his buttocks from a height of 4 or 5 feet, and who during the course of the next 2 hours developed a paraplegia. Spinal puncture was impossible and roentgenograms revealed only Marie-Struempell's disease. The sensory level was over the hands and corresponded more or less to the sixth or seventh cervical segment. Operation was performed 6 hours after the injury and a localized extradural hemorrhage was discovered beneath the seventh cervical lamina posteriorly and in the midline. This clot measured 4 by 2 by 1 cm. Over the period of the next month the patient made rapid progress. The sensory level disappeared in 2 or 3 days and movements returned to the legs in 3 or 4 days. After 3 weeks, he was returned home, and after a period of a few more weeks he resumed his usual occupation and was apparently normal.

There is a short review of the English and American literature on this subject.

Asenjo, A., Contreras, M., and Espinoza, J.: Intraspinal Lipomas (Lipomas intraspiniales). *Arch. soc. cir. hosp.*, 1945, 15: 773.

The author was able to collect from the literature not more than 38 cases of spinal lipomas. Of 15 intraspinal tumors removed at the Central Institute for Neurosurgery and Neuropathology, Santiago, Chile, 2 were lipomas, one being intramedullary and the other extramedullary. Intrathecal, extradural lipomas were not considered. The extramedullary tumor was found in an infant 1 year of age. The very large tumor originating in the second cervical segment was removed, but the child died following the laminectomy. The intramedullary lipoma was found in a man aged 44 years. This patient recovered after the operation. In both cases signs of compression of the spinal cord were present.

While lipomas in the brain cannot be diagnosed, those in the spinal cord can be recognized because of the symptoms of compression of the spinal cord. In the great majority of cases the lipoma is situated in the midline of the posterior aspect of the spine. The cervicothoracic region is most frequently involved.

There is a general consensus of opinion that lipomas are always of congenital origin. They frequently coexist with certain malformations, such as spina bifida, meningocele, meningomyelocele, and cutaneous lipomatosis.

Mycelography after lipiodol injection is of inestimable value in the diagnosis. JOSEPH K. NARAT, M.D.

SYMPATHETIC NERVES

Fontaine, R., and Eck, F.: The Usefulness of Low Lumbar Sympathectomies in Surgery of the Obturator Nerve as an Auxiliary Method in the Treatment of Spastic Paraplegias in Pott's Disease (*De l'utilité des sympathectomies lombaires basses accoudees aux traitements des paraplegies spasmotiques*). *Rev. chir., Par.*, 1945, 64: 161.

Pott's disease with spastic paraplegia offers a much better prognosis than the flaccid type of case. Sympathectomy is valuable only in association with the basic orthopedic and medical treatment.

Surgery is indicated only when paraplegias persist after the general condition has become excellent and the sedimentation rate is nearly normal. Laminectomy and bone graft constitute the treatment of choice. The lower lumbar sympathectomy is preferable to the higher one as it can be easily combined with surgery of the obturator nerve. The surgery of the nerve consists either in crushing and alcohol injection or, in extreme spasm of the adductors, in resection of the nerve. WERNER M. SOLMUTZ, M.D.

Crutcher, R. R.: Sympathectomy for Ischemia Following Femoral Artery Ligation. *Ann. Surg.*, 1946, 123: 304.

The author, apparently working in a general hospital in the Italian theater of war, discusses his experiences with 5 patients who had sustained transection of the superficial femoral artery below the profunda femoris branch.

One patient was returned to duty 3 months later suffering only from slight intermittent claudication. Three patients were subjected to lumbar sympathectomy 2 months after wounding because of persistent coolness of the affected foot, deficient acral arterial pulsations, and intermittent claudication on walking short distances due, the author believes, to persistent relative ischemia of the leg muscles. In all 3 patients the ability to walk without pain was improved, as were the color and warmth of the foot.

One patient had a lumbar sympathectomy performed at the time of the initial surgery and ligation of the femoral artery because the leg was cyanotic and pulseless. One wonders, however, in this case why procaine injection of the sympathetic chain was not performed instead of sympathectomy since the vascular phenomena appeared to be only an acute vasospasm associated with injury to the femoral artery.

In the 3 cases in which late sympathectomy was performed for persistent intermittent claudication, the clinical results were good and the patients evi-

dently benefited; at least the period of hospitalization was materially shortened.

Sympathectomy has a place in the late treatment of patients who present persistent vascular phenomena following injury of the major vessels.

LAURENCE M. WEINBERGER, M.D.

Southworth, J. L.: The Role of Sympathectomy in the Treatment of Immersion Foot and Frostbite. *N. England J. M.*, 1945, 233: 673.

The clinical syndrome of frostbite, and its more specialized form, immersion foot, which occurs after prolonged exposure in water, is of great military importance. Sixteen cases of immersion foot and 7 cases of frostbite from the U.S. Marine Hospitals at Staten Island, New York, and Savannah, Georgia, are presented.

Pathologically, changes begin with endothelial damage of the small vessels and proceed to tissue necrosis and nerve fiber degeneration. An important role is played by secondary infection. Many of the sequelae are caused by subsequent fibrosis.

Initially, analgesia and numbness of the extremity are manifest. With the return to a normal temperature, redness, edema, ecchymoses, pain, and bleb formation occur. Brownrigg has divided frostbite into first, second, and third degree types. Frostbite of the first degree is characterized by ecchymosis of the ankle and leg, hyperemia, and bleb formation; it follows a fairly mild course and leaves little or no disability. The second degree type superimposes some tissue death of the distal parts which may later require amputation. Seventy-five per cent of the patients have residual complaints of a neuritic or vasospastic nature plus the disability of the amputation. Third degree cases are those with gangrene of the deeper tissues, and amputation above the ankle is the rule. Later complications are rare except for the handicap resulting from amputation.

Early treatment consists of cooling the involved part. Sulfonamides and penicillin are given, as well as potassium permanganate soaks in cases in which dermatophytosis is present. When amputation is necessary, the author uses refrigeration anesthesia.

Late manifestations are disturbances in cutaneous sensation, inadequate circulation, and pain. The sensory changes range from anesthesia through all modalities, to dissociation of touch from pain and temperature. Near the area of anesthesia, hyperesthesia is present. Usually these symptoms disappear within from 3 to 12 months, but they may persist longer. Discomfort in walking, and frequently trophic, perforating ulcers secondary to other trauma but dependent on disturbed sensation, occur.

Inadequate circulation varies from case to case, according to factors at present obscure. This is manifested by hyperhidrosis and cold, wet, pallid feet which become cyanotic and mottled with exposure to cold. Less frequently intermittent claudication is present for a period. Sometimes in 12 to 18 months after the immersion foot or frostbite has

been sustained, the skin becomes thin, atrophic, red, and glistening. Fibrosis takes place with decreased agility of that part and amputation may be necessary. The chief disability of immersion foot is pain with walking. This is deep seated, dull, and aching. Often neuropsychiatric symptoms are precipitated by frostbite, and these may be more important and severe than those due to exposure to cold.

Repeated sympathetic blocks have been observed to hasten the healing of "civilian" frostbite and have no deleterious effects. The author's study is concerned with sympathectomy for the treatment of the sequelae of frostbite and immersion foot. Either the block or the surgical extirpation is recommended for the disturbance of cutaneous sensitivity and the circulatory insufficiency. Pain, which is often the chief complaint, is not benefited by sympathectomy, physiotherapy, or mechanical devices. Choice of the procedure — temporary block of the sympathetic chain, alcohol injection, or excision — depends on the severity of the symptoms.

Of the 23 patients presented, there were 6 first degree, 14 second degree, and 3 third degree types of frostbite. Symptoms had been present all the way from immediate possession in 27 years, this dating from World War I. Alcohol sympathetic injection was done in 9 cases, multiple procaine block in 4, and sympathectomy in 3 cases, 5 patients were treated with physiotherapy, and in 1 instance amputation alone was done. The patients receiving physiotherapy benefited little, or not at all. The others showed improvement, with 2 exceptions.

The Flathow approach is recommended for lumbar sympathectomy. When lumbar sympathetic alcohol injection is done, the author believes that one first lumbar ganglion should be spared—"to avoid dis-

turbances of the ejaculatory power." Care should be taken to avoid spearing any somatic nerves when injecting alcohol, to prevent subsequent paresis. This is managed by the use of a small amount of procaine in the skin and subcutaneous tissue, with reinstituting the needle at a different level until pain be experienced down the leg, in the hip, or in the genitals. Temporary block is given by 1 to 2 c.c. of procaine or metycaine; 4 c.c. of absolute alcohol is used for a more permanent block.

Thoracic sympathetic block is more difficult, and indications for operative sympathectomy should be more demanding than in the lumbar region. The first and second thoracic ganglia are anesthetized for therapeutic or diagnostic block of the sympathetic supply to the upper extremity. After the patient has been placed in the lateral or prone position, a wheel is made two fingerbreadths opposite the seventh cervical vertebra. A needle is inserted medial to the transverse process is met, then worked past the inferior border, and to the lateral aspect of the vertebral body. Aspiration is done to avoid intracranial injection. Five cubic centimeters of procaine or 4 c.c. of absolute alcohol are introduced when the needle is properly located. This is determined by the injection of 2 c.c. of procaine and the needle is placed correctly, vasodilatation occurs. The same procedure is carried out opposite the next thoracic spine for T₂. Since it is practically impossible to block the thoracic sympathetic ganglia without affecting the first and second thoracic nerves, these are deliberately injected when alcohol is used. Apical pneumothorax is possible when the pleura is pierced, but is not dangerous unless the patient is emphysematous.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Bronstein, I. P., and Cassoria, E.: *Breast Enlargement in Pediatric Practice. Med. Clin. N. America*, 1946, 30: 121.

Breast enlargement in children has been defined as an involvement of the mammary tissues in which these structures simulate the size, the shape and, at times, the function of the adult female breast. The authors give the following classification of breast enlargement in childhood:

1. In the newborn
2. Preadolescent type
 - (a) Transient and persistent
 - (b) Pseudogynecomastia
3. Associated with obvious endocrinopathies
 - (a) Gynecomastia, hypogonadism, excessive urinary gonadotropin excretion
 - (b) Sexual precocity
 - (c) Addison's disease
 - (d) Tumors of the testes
 - (e) Thyroid affections
4. Artificially induced
 - (a) Gonadotropins
 - (b) Estrogens
 - (c) Testosterone
 - (d) Corticosterone
5. Miscellaneous
 - (a) Liver cirrhosis
 - (b) Leucemia
 - (c) Tumors (malignant, very rare)
 - (d) Massive involvement in girls
 - (e) Associated with atrophy of the testicle following orchitis and trauma

Breast enlargement in the newborn. A high percentage of newborn infants show some breast swelling by the fifth or sixth day. About two-thirds of these secrete a colostrumlike fluid followed, usually, by small amounts of milk. Instances of secretion persisting up to 12 months have been reported. These breasts are histologically miniature lactating glands attaining their development through the influence of placental transmission. The enlargement disappears spontaneously within a variable period. Treatment should not be attempted.

Preadolescent breast enlargement. Transient and persistent types occur in boys usually between the ages of 13 and 18, and in girls usually between the ages of 8 and 12 years. The swelling, either unilateral or bilateral, varying in size from 2 to 5 cm. in diameter, forms a roughly spherical tumor directly behind the nipple. Histological examination reveals an increased physiological hypertrophy of the pericanalic-ular and pericanalic-ular tissues similar to that observed after estrogenic administration. The course is not predictable. Some of the swellings disappear completely within a few weeks, others last for years. In

the persistent cases of breast enlargement in males, traced back to adolescence in which operation was done in young adulthood, the microscopic picture is similar to that found in chronic cystic mastitis in the female.

No instance of malignancy is reported in the patients with long-standing preadolescent breast enlargement. Most of these breast enlargements involute spontaneously within a few months. Surgical intervention may be advisable if there is no tendency to involution, and especially if personality changes become prominent.

Pseudogynecomastia. Breast enlargement in this condition, occurring in both girls and boys, is a part of the general picture of the obesity involving also the girdle and suprapubic areas. The involvement is bilateral, is unassociated with discomfort, and tends to assume the size and shape of the adult female breast. Gland tissue is not ascertainable, the swelling being apparently formed by adipose tissue. In the therapy of obese children, endocrine treatment did not cause any alteration in the redistribution of fat. With the general loss of weight the breast condition is also rectified.

Breast enlargement associated with obvious endocrinopathies. The syndrome of gynecomastia with small testes, aspermatogenesis, and excessive urinary gonadotropins has been noted in adolescent boys, and testosterone therapy was partially effective.

Sexual precocity. Breast enlargement may be one of the striking symptoms of sexual precocity. Instances of sexual precocity have been associated with a variety of conditions, i.e., hypothalamic lesions, osteodystrophia fibrosa disseminata, ovarian tumors, adrenal cortical tumors, and hyperplasia. Breast enlargement associated with Addison's disease, tumors of the testis, and thyroid affection is rare in childhood.

Breast enlargement resulting from administration of hormones. Chorionic gonadotropins have produced breast swellings when the material was administered for cryptorchidism. The doses administered in these conditions are not very great (3,500 to 7,000 rat units) and the breast enlargement, which is usually slight, disappears when the drug is discontinued.

Estrogens. Preadolescent girls with gonorrheal vaginitis treated with stilbestrol have developed breast enlargement which disappears with cessation of therapy. Oral stilbestrol therapy has been employed in male hypersexualism, and gynecomastia has appeared after the use of 375 mgm.

Testosterone and Corticosterone. Gynecomastia has been observed in some cases following the use of these substances.

Miscellaneous conditions associated with gynecomastia are rare, and have been enumerated in the classification.

ERNEST E. ARNHEIM, M.D.

Warren, S.: The Prognosis of Benign Lesions of the Female Breast. *Surgery*, 1916, 10: 32.

Although a large and as yet undetermined number of cancers of the breast appear to arise without antecedent pathological change, certain benign lesions predispose to the development of malignant mammary tumors. Some of these lesions have been almost universally regarded as precancerous, while some controversy has existed as to the significance of others. At least a portion of this uncertainty was based on confusion in terminology of the lesions. In any attempt to classify lesions of the breast certain points must be kept in mind.

1. Hypertrophy. At or following puberty, one or both breasts may enlarge to an excessive degree. The enlargement does not produce symptoms other than those referable to its size. The consistency is essentially that of a normal breast. On section the breast tissue is diffusely fibrotic with increase in the connective tissue elements and sometimes associated with periductal edema. Assays of the urine of these patients for estrogenic hormones usually show the estrogens to be within normal limits, although they may be slightly elevated. This condition does not predispose to the development of carcinoma.

2. Adenofibrosis. The breast with the lesion of adenofibrosis is diffusely fibrotic or finely nodular. In the early stages it shows cyclic swelling, more noticeable premenstrually and lessening with menstruation. Later, the slight to moderate increase in size becomes permanent. Pain is ordinarily more severe in the premenstrual period and is relieved by menstruation. The swelling and pain may be accompanied by venous engorgement. Study of the hormonal output has not revealed definite abnormalities. This condition rarely persists beyond the menopause, it is not known to be precancerous.

3. Chronic mastitis. The lesion of chronic mastitis is probably basically adenofibrosis with epithelial proliferation of a mild type or abnormal secretory activity of the mammary epithelium superimposed. There may be serous discharge from the nipple. On palpation, granular or nodular and, at times, firm cordlike structures may be felt, often radiating out from the region of the nipple. The nodules are not hard but somewhat elastic. At times the breast may reveal foci of closely packed, almost solid masses of ductal and acinar epithelium, which superficially resemble neoplasia. These foci are actually benign in spite of the somewhat bizarre and highly cellular picture that they may present. In its more marked forms, this condition, unlike adenofibrosis, may persist after the menopause. The lesion is probably due to endocrine dysfunction in which the normal cyclic character of the secretion of estrogens has been disturbed, and the process might be caused by continuous estrogenic stimulation lacking the counterbalance of an adequate production of corpus luteum hormone. In its milder forms this lesion is not precancerous, but in those in which marked epithelial hyperplasia occurs it must be considered precancerous.

4. Chronic cystic mastitis. This presents a number of forms. The one common factor is the development of cysts readily visible, single or multiple. These may have entirely lost their epithelial lining, the cysts are lined with essentially normal epithelium, or they may be lined with epithelium showing various degrees of hyperplasia and intracystic papillary proliferation. Chronic cystic mastitis is most common toward the end of the childbearing period and just after the menopause. Adenofibrosis or chronic mastitis may precede the development of chronic cystic mastitis. Pain is usually absent. Cyclic swelling is not an integral part of the process. A lump in the breast, either localized or generalized, is the clinically distinguishing feature. It can be clearly emphasized that given an isolated nodule in the breast, it is impossible to distinguish by physical examination between localized cystic disease and early carcinoma. The nature of such a lesion should be determined by biopsy. The presence of a typical blue domed cyst is no guarantee that the remainder of the breast tissue is normal and free from malignancy. On microscopic observation there may be found a single flattened layer of epithelium lining the cyst, or this may have atrophied and left fibrous tissue alone. There is every gradation from the atrophic lining through several layers of proliferating epithelial cells to the active proliferation lining the duct with evidence of cellular anaplasia and mitotic activity, which lacks only the occurrence of the invasion to warrant the diagnosis of carcinoma. Since by external examination there is no way of distinguishing between those forms of chronic cystic mastitis which show little or no epithelial activity and those which show marked epithelial hyperplasia, the disease must be considered as precancerous.

On the basis of certain studies, the following general rule for the management of chronic cystic mastitis is presented. If the chronic mastitis is localized and the woman is under 35 years of age, it is particularly desirous of keeping her breasts as long as possible without further therapy beyond the removal of the palpable mass is immediately indicated. Such a patient should be followed up at semiannual intervals and if a further mass develops, either a simple mastectomy or a radical mastectomy should be performed according to whether the mass is of firm, solid type, benign or malignant. Since the lesions in chronic mastitis and chronic cystic mastitis are actually bilateral, the logical procedure would be to remove both breasts. There is not sufficient proof of the subsequent development of carcinoma, however, to warrant or justify bilateral mastectomy. If the excision of a focus of chronic cystic mastitis or chronic mastitis, there is found evidence of benign or precancerous hyperplasia, a simple mastectomy should be performed on the affected breast.

5. Intralobular papilloma. Intralobular papilloma of the breast is essentially a benign papillary mass projecting into the distended lumen of a duct. The papillary mass is made up of completely benign

stromal bands often arranged in a frondlike pattern and usually attached at only one point to the wall of the duct. The epithelium is usually cuboidal, rarely columnar. The most common site is within 2 cm. below the areola, although it may be found elsewhere along the course of the ducts. The attachment of the intraductal papilloma is usually by a single stalk, although there may be several attachments. Since the stroma is quite vascular, oozing may occur from its blood vessels, and either bloodstained or frankly bloody discharge from the nipple may result. These tumors are rarely bilateral. Four types of papillary lesions are recognized: papillary hyperplasia in adenosis, papillary invaginations too small to be palpated but which produce bleeding at the nipple, benign intracystic papilloma, and papillary cancer. Excision of a grossly recognizable intraductal papilloma may leave others still present in the breast tissue. For this reason there is a predisposition to the subsequent development of carcinoma in a breast from which such a lesion has been excised. There is not a sufficient number of cases to permit any statement beyond the one that the occurrence of intraductal papilloma seems to predispose to the development of carcinoma in a breast and this lesion is more apt to predispose to the development of carcinoma than any other encountered in the breast.

6. Fibroadenoma. This is usually a single but sometimes multiple lesion of the breast, sharply circumscribed and freely movable. Usually spherical or ovoid, its contour may be slightly nodular. On exploration, the tumor is easily separated from the breast tissue. There is some evidence that these tumors are more frequent in nulliparous women with underdevelopment of the breasts. As has been frequently pointed out, a fibroadenoma which occurs in a woman near the menopause is somewhat more apt to become sarcomatous than one developing in a younger woman. Fortunately, adenofibrosarcoma is apt to be of low grade malignancy and rarely metastasizes to the regional nodes. Although local rather than radical mastectomy may be adequate therapy, the possibility of metastasis to axillary nodes must be kept in mind. Fibroadenoma of the breast does not predispose to the development of mammary carcinoma.

STEPHEN A. ZIEMAN, M.D.

Shlnkin, M. B.: The Experimental Induction of Mammary Cancer. *Surgery*, 1946, 19: 1.

Studies on the genesis of mammary tumors of mice indicate that the neoplastic reaction is the end result of an intricate interplay of at least four factors or complexes of factors:

1. The genetic constitution of the mouse influences mammary tumor development by determining the susceptibility of the mammary tissue to the hormones and the milk agent by modifying or altering the mechanism of hormonal stimuli, and by determining the animal's resistance to the milk agent and its transmission. Genetic factors influencing this susceptibility are multiple. The ability of the animal

to propagate the milk agent and susceptibility to mammary cancer may be governed by a separate set of genes.

2. Hormonal stimuli are essential for the development of the breast and for the creation of a suitable substrate for the action and interaction of other factors that eventuate in the development of mammary tumors. There is no evidence that the hormonal complex must be abnormal, either qualitatively or quantitatively, for the genesis of mammary tumors in mice. Alterations induced in the hormonal balance by the addition or withdrawal of estrogens and other hormones modify the processes that lead to the development of tumors.

3. The milk agent, transmitted through the milk of the mother, is necessary for the appearance of most of the mammary tumors in mice. The virus nature of this agent is not established. However, if it is a virus, the appearance of mammary tumors would be influenced by variations in the virulence of the agent under various conditions.

4. Various other environmental factors, such as diet, temperature, and overcrowding, also affect the genesis of mammary tumors, probably by modifying the growth and development of the tissues and of the hormonal secretions of the animal.

There is no evidence in the literature to prove that even protracted use of estrogenic substances has been instrumental in producing mammary carcinoma in women. The possibility of carcinogenesis due to the protracted use of these agents cannot be overlooked however, nor the danger of using such preparations for the treatment of breast masses diagnosed clinically as benign, which leads to procrastination in surgical intervention for possible early carcinoma.

Cystic disease and other benign masses of the breast in women increase the risk of carcinoma.

In all species, a degree of genetic susceptibility and a degree of hormonal stimulation are essential for the development of cancer of the breast. The process can be modified by numerous secondary factors of internal and external environment. Although it is possible that the fundamental mechanism of transformation of normal cells to malignant neoplasms is the same for all types of cells and all species of animals, the inciting factor leading to the development of the malignant state are obviously different for different types of neoplasia and different species of animals.

It is possible that not all mammary cancers in one species can be grouped etiologically. For example, it is not established that the mammary cancers of mice in which the milk agent is operative are the same as those induced by methylcholanthrene.

Extrapolation from one species to another and from one type of tumor to another is not warranted at this early stage in the knowledge of the nature of neoplastic reaction. It is sounder to accentuate the careful, patient analysis of each possibly divergent type of cancer, with the hope that eventually this information may be synthesized into a coherent whole.

SAMUEL KANE, M.D.

Foot, F. W., Jr., and Stewart, F. W.: A Histological Classification of Carcinoma of the Breast. *Surgery*, 1946, 19: 74.

In the classification scheme offered by the authors, carcinoma of the breast has been classified, in so far as possible, as to site of origin and, hence, the nipple has been taken as a starting point, followed by the ducts and lobules, and, finally, certain relatively rare or highly unusual histological types of cancer have been enumerated. Certain forms of mammary cancer such as carcinoma en cuirasse and inflammatory carcinoma are omitted as they do not have histological specificity.

Histological classification of carcinomas of the breast:

1. Paget's disease of the nipple
2. Carcinomas of the mammary ducts
 - a. Noninfiltrating tumors
 1. Papillary carcinoma
 2. Comedocarcinoma
 - b. Infiltrating tumors
 1. Papillary carcinoma
 2. Comedocarcinoma
 3. Carcinoma with productive fibrosis
 4. Medullary carcinoma
 5. Colloid carcinoma
3. Carcinomas of the mammary lobules
 - a. Noninfiltrating
 - b. Infiltrating
4. Relatively Rare Carcinomas
 - a. So-called sweat gland carcinoma
 - b. Intracystic carcinoma
 - c. Spindle cell carcinoma, "adenosarcoma"
 - d. Adenoid cystic carcinoma
 - e. Carcinoma with osseous and cartilaginous metaplasia
 - f. Squamous carcinoma
 - g. Malignant variant of fibroadenoma and cystosarcoma phyllodes

The clinical implications of Paget's disease of the nipple are, for the vast majority of cases, quite clear cut and they indicate the necessity for radical amputation of the breast. Even in Paget's disease of the nipple, in which there is no clinically palpable underlying lesion, one undertakes considerable responsibility when recommending any procedure short of radical mastectomy. Metastases have been found in Paget's disease when no definitive tumor was palpable. Sections from such cases have shown the presence of miniature infiltrating carcinomas.

It is very difficult in some cases to be certain from frozen sections that there is no infiltration in non-infiltrating papillary carcinomas. Under these circumstances the authors recommend simple mastectomies. If no infiltration is found after study of subsequent paraffin sections, further operative procedure is unnecessary. If, however, the tumor is shown to be infiltrating, it is obligatory that radical dissection be carried out.

A true noninfiltrating comedocarcinoma represents another example of breast carcinoma which may be rationally treated by simple mastectomy.

The practice of aspiration biopsy carries a delay in the correct diagnosis of infiltrating papillary carcinoma. In those cases in which local excision is done, the gross aspect or, if needed, frozen section will disclose the true nature of the tumor, and the radical operation can then be carried out. Cautiousism is unwarranted in spite of the better prognostic outlook.

Tumors comprising the group of infiltrating duct carcinomas with productive fibrosis are far and away the most common forms of mammary cancer, aggregating roughly 70 per cent. Included here are the tumors that may be summed up as the "ordinary mammary scirrhus." The macroscopic characteristics of these tumors are easily recognized, and these are the forms of mammary carcinoma usually described when the classical gross traits of mammary carcinoma are enumerated. The majority of these tumors are not rounded, but are discoid and have distinctly irregular edges which radiate from the general periphery of the tumor into the adjacent fibrous or fatty breast tissue. An outstanding attribute is firm and almost unyielding induration. Radical mastectomy is the only approved surgical procedure for tumors of this infiltrating group.

Grossly, medullary carcinomas have highly distinguishing qualities. They are commonly quite bulky, measuring 4, 5 and 6 cm. in diameter, and now and then these dimensions are doubled. They are rounded or globoid, may be cut with little resistance, and although not encapsulated they are distinctly circumscribed and present a smooth periphery. As a rule the axillary nodes do not contain tumor unless the primary growth is as large as from 15 to 2 cm., and the tumors may reach a very large size or even fungate without having metastasized to the axilla. They constitute from 15 to 20 per cent of the breast carcinomas. In surgical control of this disease, radical mastectomy is again the only procedure that can be properly advised.

Lobular mammary carcinoma *in situ* cannot be diagnosed clinically, nor can a diagnosis be made on gross pathological examination. For this reason, this form of noninfiltrating carcinoma represents an incidental finding in local excisions which have been done for presumably benign conditions. The only physical sign elicited when this lesion exists is a defined induration, and this only in the exceptionally well developed case. Simple mastectomy should be done when the diagnosis of lobular carcinoma *in situ* is made, and if, in subsequent pathological material, infiltration is discovered, further surgical procedure is necessary.

Infiltrating lobular tumors make up from 5 to 10 per cent of all breast carcinomas. Infiltrating globular carcinomas are more apt to resemble scirrhus carcinomas than any other gross anatomic type. The tumors, as a rule, are discoid or somewhat irregular in shape and are rather poorly demarcated. They are tough and firm, but are less apt to show the chalky streaks so common in the ordinary mammary scirrhus. These tumors are fully aggressive and

mary cancers and as such call for radical surgical measures.

There are no unique characters that make it possible to identify so called sweat gland carcinomas. Ordinarily they resemble the more cellular infiltrating duct carcinomas with more or less productive fibrosis. The therapeutic implications of infiltrating mammary carcinomas apply here. If perchance a noninfiltrating form is encountered, simple mastectomy should suffice.

If the malignant alteration of a fibroadenoma is met with in an early phase, and is confined to the lining epithelium, or at most not extending beyond the capsule, the disease can be controlled by local excision or simple mastectomy, in accord with the extent of the change. With infiltration radical mastectomy becomes necessary.

JOSEPH K. NARAT, M.D.

Harrington, S. W.: *Survival Rates of Radical Mastectomy for Unilateral and Bilateral Carcinoma of the Breast. Surgery, 1946, 19: 154.*

The mammary gland is one of the most common sites of malignant disease in women. There are essentially two types of primary malignant neoplasms of the breast, carcinoma and sarcoma. The former is the principal type of malignant lesion occurring in the mammary gland.

Statistical studies have been made on all patients on whom radical operation has been performed at the Mayo Clinic for malignant disease of the breast from the years 1910 to 1940, inclusive; they comprise a series of 6,558 cases. Forty-seven patients (0.7 per cent) died in the hospital following operation; and of the 6,511 patients who recovered from the operation, 6,318 (97.0 per cent) were traced for 3 or more years.

These studies have been made primarily to determine the results of radical surgical treatment as well as to point out some of the clinical or pathological factors that influence the prognosis. In all of the statistical studies of survival rates it has been assumed that the patient died of malignant disease, although in many instances it was definitely known that death was due to other causes.

The first study in detail was made on the entire series of malignant lesions of the breast treated by radical mastectomy from 1910 to 1940, inclusive. All cases were included: those of carcinoma, sarcoma, unilateral and bilateral disease, and females and males. The objective of this study was to determine the influence that the extent of the disease, as indicated by the presence of axillary nodal metastasis when found at the time of the operation, had on the prognosis.

There was a wide variation in the survival results and the prognosis was much better in the cases in which axillary nodal metastasis was not found at the time of operation than in the cases in which axillary nodal metastasis was found. The patients who did not have axillary metastasis at the time of operation constituted 40 per cent of the entire series. The

proportion of this group of patients living 3 years or more after operation is 85.0 per cent or almost twice as large as that of the group with axillary metastasis which was 45.3 per cent. In the 5, 10, 15, and 20 year survival rates of patients without axillary nodal metastasis, it is found that the improvement increases progressively over the group with axillary metastasis. For the 5 year period, the survival rate for the group without metastasis is two and a half times as large as that for the group with metastasis; for the 10 year period it is three and a half times as large; for the 15 year period it is four times as large and for the 20 year period it is more than five times as large.

Studies of survival rates in special groups such as of carcinoma, sarcoma, unilateral and bilateral disease, and males and females were all included in the complete article. All of the different classifications and types of carcinoma were divided into two groups, those in which axillary nodal metastasis was present and those in which it was not present at the time of operation.

Adair, F. E., and Herrmann, J. B.: *Sarcoma of the Breast. Surgery, 1946, 19: 55.*

From 1926 to 1944, inclusive, 5,499 examples of malignant breast tumor were seen at the Memorial Hospital, New York, New York. Of these, 30, or 0.5 per cent, were sarcomas. The higher percentage of sarcoma found by the earlier investigators may possibly be due to the inclusion of some small round cell and spindle cell neoplasms which were formerly classified as sarcomas but were in all probability atypical carcinomas.

Among the 30 sarcomas the following types were encountered: cystosarcoma phylloides (malignant), adenosarcoma, fibrosarcoma, spindle cell sarcoma, angiosarcoma, liposarcoma, lymphosarcoma, Hodgkin's sarcoma, carcinosarcoma, and myosarcoma.

It is accepted by numerous investigators that many sarcomas and an occasional carcinoma may arise on the basis of a previously existent fibroadenoma. In the course of development of some sarcomas, the connective tissue elements may obliterate the epithelial components and produce an almost pure sarcoma such as the fibrous and spindle cell varieties. In others the epithelial elements may persist and both structures may manifest malignant characteristics, as in cystosarcoma phylloides and adenosarcoma.

The diagnosis of breast sarcoma in most instances necessitates the differentiation of this condition from cyst or carcinoma. The history is frequently suggestive of sarcoma. In these instances the patient states that a tumor has been present, although quiescent, for a considerable length of time. Suddenly it begins to increase rapidly in size. This occasionally follows a trauma. A cyst may exhibit the same phenomena although in the latter condition there is rarely the history of a pre-existent tumor. The spherical, cystic property of the mass and its capacity to transilluminate suggest that the tumor

may be a cyst. Sarcoma is not translucent except in those forms of *cystosarcoma phylloides* which are more cystic than solid.

Carcinoma may be suspected if there is skin dimpling or nipple retraction. These are seldom observed in sarcoma unless the tumor becomes so large that it impinges on the overlying skin. Then it may produce attachment, redness, and ulceration. Occasionally a diffuse duct carcinoma may produce great enlargement of the breast and in this respect simulate sarcoma. However, the diagnosis of sarcoma may be difficult or impossible to establish by clinical means. Aspiration biopsy in most instances will furnish the requisite information.

Sarcomas are usually very vascular. There is metastasis to distant organs in from 12 to 18 per cent of the cases. In order of frequency these organs are the lungs, liver, brain, dura mater, pleura, the mediastinal, retroperitoneal, and axillary nodes, the heart, kidney, and bones. Despite an apparent cure of a breast sarcoma it is possible for a metastatic focus to appear after many years. This, however, is an unusual phenomenon. Lymphatic channels have not been described in sarcoma. For this reason the lymphatic spread of the disease with invasion of the lymph nodes, except in lymphosarcoma, melanosarcoma, and carcinosarcoma, is necessarily a rare phenomenon. Although axillary and supraclavicular lymph nodes may be palpable, the enlargement in most instances is the result of an inflammatory rather than a metastatic process. In the authors' series 4 patients had palpable axillary nodes. A study of 100 radical mastectomies for sarcoma collected from the literature reveals lymph node invasion in 4 per cent.

An analysis of the results of surgical therapy would indicate that conservative procedures are as effective as radical measures. Since there is evidence that breast sarcoma owes its inception in some instances to malignant deviation of a fibroadenoma, this tumor should be removed early. Early removal is also the best method for preventing metastatic spread if sarcomatous change has already occurred. If the tumor is small and of low grade malignancy, simple excision should suffice. If larger or of a higher degree of malignancy, a simple mastectomy with removal of the pectoral fascia is indicated. The more malignant forms have the tendency to infiltrate the underlying muscle and give rise to recurrences. For that reason, in situations where there is evidence of this possibility the *pectoralis major* muscle should be removed. Radical mastectomy is the procedure of choice in primary lymphosarcoma, melanosarcoma, and carcinosarcoma.

Since breast sarcoma is an unusual lesion there has been relatively little opportunity to determine the therapeutic effect of irradiation on these tumors. Postoperative x-ray treatment may be of value in very cellular tumors and in those which manifest infiltrative tendencies. There is also a possibility that the vessels adjacent to the excised tumor or breast tumor may contain tumor thrombi. Under

these circumstances radiation therapy might prove advantageous. It is quite possible that in some forms of breast sarcoma the incidence of recurrence and metastasis may be materially decreased by irradiation. Until enough data have been accumulated, a definite conclusion cannot be reached.

The prognosis is dependent upon the type of the neoplasm. Sarcoma is a generic term for a number of new growths which have in common their origin from mesodermal elements. These tumors vary in their malignant potentialities. At one end of the scale is the low grade malignant variant of *cystosarcoma phylloides*, and at the opposite extreme is the highly malignant angiosarcoma. This classification is subject to further division because there are variations in degree of malignancy within the groups. Thus, the prognosis depends not only on the type of sarcoma but also on the grade of the particular lesion within the group.

Age is also a factor. Sarcoma tends to occur in relatively young women. Sarcoma occurring in a functionally active breast evinces a morbid disposition to recur after operation with less disposition to metastasize, whereas a sarcoma of the declining breast recurs less frequently but metastasizes in a greater number of instances. This generalization does not appear to apply to angiosarcoma.

Local recurrence, regardless of the surgical procedure employed, is a frequent occurrence but does not necessarily imply a poor prognosis.

It has been frequently stated that sarcoma of the breast offers a better prognosis than carcinoma of this organ. This depends upon the variety and grade of the sarcoma. Certainly angiosarcoma is much more malignant than most cancers and, conversely, low grade fibrosarcoma and liposarcoma are much less malignant than low grade carcinoma.

JOSEPH K. NARAY, M.D.

TRACHEA, LUNGS, AND PLEURA

Rousseau, R. G., Abat, O. D., and Medrano, F. A.: Primary Epithelioma of the Trachea (Epithelioma primitivo de la tráquea). *Arch. cubanos cancerol.* 1945, 4 275

The authors present a brief review of the literature and a report of 4 cases, 1 having been seen by them recently, 1 studied 6 years before, and 2 seen by other local physicians.

The first tracheal neoplasm was probably recognized in 1767, and in 1871 Langhans described the first case of primary tracheal epithelial neoplasm. Collected series of neoplasms reveal a low percentage incidence in the trachea. When compared to laryngeal neoplasms, the incidence is variously reported as 3 to 748; 4 cancers of the trachea to 800 of the larynx, or 2 epithelial tumors of the trachea to 517 of the larynx. According to Chiari, cancer is the most frequent of the primary tracheal neoplasms.

The distribution of tracheal tumors is roughly 50 per cent in the lower third, 35 per cent in the upper third, and 15 per cent in the middle third.

Men are more often affected than women, in a 2 to 1 proportion. The age group most frequently involved is between 50 and 70 years.

The symptoms are cough, sometimes productive of blood and dyspnea. Dysphonia is sometimes noted, probably as a result of mediastinal invasion, which is common and involves the recurrent laryngeal nerves.

Diagnosis is made only by tracheoscopy and biopsy. Indirect laryngoscopy may permit visualization of some of the neoplasms. Bronchography may give suggestive evidence. The prognosis is unfavorable and life expectancy ranges from 6 to 18 months.

Treatment has consisted in excision with or without electrocoagulation, performed endoscopically or by open operation resection or repeated cauterization. Radium has been used. The authors used deep roentgen therapy in 2 of the cases reported. Electroexcision and radium are suggested as therapeutic methods. Photomicrographs of a tumor and a reproduction of a bronchogram are appended.

A list of 85 references to the literature is given.

HIRAM T. LANGSTON, M.D.

Brewer, L. A., Burbank, B., Samson, P. C., and Schliff, C. A.: The "Wet Lung" in War Casualties. *Ann. Surg.*, 1946, 123: 343.

By "wet lung" is meant the persistence of fluid in the pulmonary tree. Since this is a very important problem in the care of the wounded, and since no reference to the problem is seen in prior literature, the authors believe that a discussion is warranted. The observations presented are based on the care of over 700 chest casualties, and the thoracic complications in over 3,000 other casualties during the Sicilian and Italian campaigns.

Two groups of factors are important in the development of the wet lung. Those in the first group are referred to as forces leading to the production of secretions or other fluids in abnormal amounts in the respiratory tract. These include (a) mucoid secretions derived from increased secretory activity of the bronchial mucosa; chest wall trauma frequently has been shown to result in widespread bronchial spasm and increased bronchial secretion; other elements such as traction on the cystic duct or mesentery may do the same; (b) blood from intrapulmonary hemorrhage is present; (c) mucopurulent secretions resulting from respiratory infections in men who have undergone the exposure of combat conditions are common; (d) fluid arises from the alveoli of the lung.

The mechanism of this production in the severely wounded is not clear, but at least four factors contribute to it: (1) pulmonary trauma, (2) increased respiratory effort, (3) tracheal obstruction, and (4) anoxia. The effects of "blast" and a late manifestation of shock may also contribute.

Other important factors in the development of the wet lung are conditions preventing adequate removal of the fluids produced. These include factors interfering with the proper functioning of the cough

mechanism, such as chest pain or abdominal pain. Rib fractures are a potent source of chest pain. Multiple fractures resulting in a "flail chest" add the factor of paradoxical motion. Caution against overdosage of morphine is stressed. Coma or unconsciousness, and prolonged anesthesia or delayed reaction of the patient are discussed. The position of the patient because of pain may favor gravitation and retention of secretions.

Early harmful effects of this condition are the improper ventilation and aggravation or production of anoxia. Plugging of branches of the bronchial tree lead to atelectasis and its attendant disturbances. Later, if the patient recovers from the primary shock and the pulmonary tree is not cleared, atelectasis, pneumonia, and tracheobronchitis are likely to follow.

The signs and symptoms of the condition should be recognized as soon as possible, and active treatment instituted. They include a "wet cough," and a wheezing or rattling quality to the cough may persist even though sputum is actually being raised by the effort. The cough may be continuous and hacking or paroxysmal. Occasionally it may even be nonproductive. Persistence of rales after coughing indicates inadequate expulsion. Dyspnea, particularly if out of proportion to the extent of trauma or pleural accumulation, is important. The post-tussive rale may vary from a high pitched wheeze to bubbling. The "oral click" is a sensitive index of moisture in the tracheobronchial tree. Tachycardia, cyanosis, more or less shock, and even coma may be present, as well as psychotic manifestations. The character of the sputum may be of diagnostic value; if mucoid, it suggests reflex bronchial stimulation, irritation by aspirated material, or early infection; hemoptysis means pulmonary injury; thin sero-sanguineous or seropurulent material suggests a bronchopleural fistula; a frothy appearance favors pulmonary edema.

The x-ray picture is not definite in the earlier stages, and may be confused with pulmonary hematoma and other conditions. Established atelectasis is, of course, definitely recognized.

Treatment begins with prevention. All cases of thoracic, abdominal, or brain injury are surveyed from this standpoint. Fowler's position is recommended for better aeration of the lungs and to prevent encroachment on the thorax by abdominal viscera. Oxygen is used as indicated and the patient is assisted in coughing. Morphine is cautiously used, preferably intravenously, since its effects can thus be better gauged. Aspiration of any pleural accumulation, sealing of sucking wounds, and relief of gastric distention are added to the usual resuscitative measures.

Active treatment consists in:

1. Intercostal nerve block for the relief of pain. The technique is briefly described. Several segments should be blocked on either side of the injured area. The benefits of this last longer than the pharmacological action of the drug, although the explanation

is not clear. Strapping, except to stabilize a "flail chest," is not necessary. Intercostal block may be beneficial beyond mere relief of pain, in interrupting reflexes which presumably result in bronchospasm and bronchorrhea. Intercostal block at the end of thoracotomy is a means of reducing postoperative pain and complications.

2. Catheter aspiration. If the patient is unable to adequately clear the tracheobronchial tree by conservative means, some mechanical method of accomplishing this is necessary. The technique of passing a catheter into the trachea and electively into either bronchus is described. The catheter produces coughing and expulsion of secretions, in addition to the amounts aspirated. In some instances, it may be left intubating and oxygen may even be given by this method. The method is effective, readily available, does not require extensive experience, or the use of a complicated apparatus.

3. Bronchoscopy. This is used when catheter suction is not sufficiently effective or when a more thorough cleansing of the tracheobronchial tree is required, such as in established or suspected atelectasis. It should be done neatly and with dispatch to prevent undue fatigue. Oxygen may be administered during this procedure.

4. Positive pressure oxygen. The constant formation of fluid in the alveoli and branches of the bronchial tree by transudation, as in pulmonary edema, cannot be satisfactorily removed by the methods listed. This method is satisfactory in retarding or preventing this phenomenon, but all accumulations from other sources and the excesses from this source should be eliminated prior to its exhibition. Positive pressure oxygen is administered from a to-and-fro system containing a soda lime canister and rebreathing bag. Pressure is maintained manually and should be kept below 10 cm. of water. The method is probably not safe for cases of severe shock, as it may seriously impede the return flow of blood to the heart.

Four illustrative case records substantiated by good roentgenograms are presented. The available experimental evidence supporting the views which have been expressed, is discussed.

HIRAM T. LANGSTON, M.D.

Bobrowitz, I. D., Edlin, J. S., Bassin, S., and Woolley J. S.: Penicillin in the Treatment of Bronchiectasis. *N. Eng. J. Med.*, 1946, 234: 147.

The present study was made to estimate the advantages of the topical or bronchial effect of penicillin in the treatment of bronchiectasis when administered intramuscularly, intratracheally, intrabronchially, and by inhalation (nebulization), singly or in combination.

Ten men and 2 women from 16 to 30 years of age were treated from August 9, 1944 to April 18, 1945, the first 9 at the municipal Sanatorium, Otisville, New York, and the last 3 at St. Clare's Hospital, New York, New York. The follow-up observations were made at the St. Clare Clinic.

Assay studies showed a lack of penicillin in the sputum of patients following intramuscular injection. Daily intratracheal instillations for more than a short period were found to be definitely undesirable.

The intratracheal route gives the most effective local concentration of the drug, an excellent topical or bronchial effect, and a good parenchymal effect with a high absorption rate, as indicated by high blood and urine levels. A short intensive course with intratracheal instillations of at least 100,000 units daily by the supraglottic method, with topical cocaineization and postural control, is suggested as suitable for preoperative preparation for lung resection. It can also provide an immediate maximum and rapid effect prior to continuation of the penicillin by inhalation, which is the simplest procedure although more drug must be used (4,000,000 units in 60 days give an optimum average sputum penicillin concentration of 86 units per cubic centimeter). Excesses are lost in the sputum.

Penicillin inhalation is not necessarily a hospital procedure. It may be resorted to in the physician's office, the clinic, or the patient's home with a vaporizer and oxygen tank. There are no evidences of toxicity over a long period of time. It is advisable to assay routinely the sensitivity of bacteria from infected foci of all patients to whom it is contemplated to administer penicillin. The question of the resistance of organisms is still unsettled and its relationship to therapy is yet to be determined.

Although destructive changes of bronchiectasis are irreversible, the present series, which includes patients who could not be treated surgically because of multilobar and bilateral involvement, shows that treatment with penicillin causes diminution of the sputum, elimination of gram positive organisms, favorable influence on gram negative organisms, clearing of foul odor, reduction in purulence, and beneficial effects on cough, dyspnea, wheezing, anorexia, weight, and nasal discharge. With cessation of therapy, cough and expectoration increased, organisms reappeared, pus cells became more numerous, and in many cases odor returned; however, the sputum level was one-half that of the original and much of the symptomatic improvement persisted.

If treatment could be prolonged with sustained effectiveness this nonoperative method might control such complications as pneumonia, lung abscess, empyema, amyloidosis, cardiac failure, and brain abscess, as well as the psychic, social, economic, and physical handicaps of bronchiectasis. Sufficient dosage for a long enough period might even lead to repair.

Prior to penicillin administration and throughout the hospitalization period, patients were kept on postural drainage 2 or 3 times a day for from 10 to 15 minutes and were instructed to continue it after discharge. Diagnosis was established by means of the bronchogram with lipiodol. Sputum was regularly measured or weighed, the odor noted, and the

presence, relative number, and kinds of organisms were noted by smear and confirmed by culture, both aerobic and anaerobic. The symptoms and physical findings were characteristic. Two cases gave roentgenographic evidence of sinus involvement.

LYNN JOHNSON, M.D.

Brown, C. J. O.: Putrid Lung Abscess. *Med. J. Australia*, 1946, 1: 107.

Putrid lung abscess is a serious and by no means infrequent complication of surgical operations and parturition. Of 41 patients operated on for lung abscesses, 21 acquired the lesion following operation or parturition.

The common factor in all 21 was general anesthesia; in most cases the anesthesia was "troublesome," or postoperative vomiting occurred. Some patients had recovered too soon from anesthesia in a dental operation, and anesthesia was reintroduced when the patient had his mouth full of blood and saliva. In one instance, teeth and tonsils, and in another tonsils and antra, were dealt with at the same operation. In yet another, although the patient was not seen to vomit, some dried vomitus was noticed on the pillow. Postoperative lung abscesses result from the inhalation of blood, pus, or debris, and it can be shown by bronchoscopy that some blood always enters the trachea during any operation on the nose or mouth unless special measures are taken to prevent it. Even in a conscious patient the laryngeal reflex is not the complete protection it is often assumed to be. Lipiodol introduced into the pharynx of a sleeping patient can be demonstrated roentgenologically in the lungs next morning, and heavy sedation is quite sufficient to put the laryngeal reflex off its guard.

If the patient is lying on his back, inhaled material tends to gravitate into the bronchus to the apex of a lower lobe—usually in the right lung—and if he is lying on his side, it flows first into the upper lobe bronchus of the lower lung. These facts can readily be demonstrated with lipiodol under the x-ray screen. Postoperative abscesses are most common in the apices of the lower lobes and in the upper lobes. After regional block anesthesia inhalation may occur while the patient is "sleeping it off," and heavy sedation should be avoided in these patients.

The blood aspirated into the lungs after the majority of mouth and nose operations, is coughed up and causes no trouble. In some a small bronchus becomes blocked by the inhaled material, and the corresponding segment of lung becomes atelectatic; with infection added, a localized pneumonitis develops, and this is the explanation of many postoperative pneumonias. When the infecting organisms are necrotizing dental anaerobes or similar types, a putrid lung abscess results. The segment of atelectatic lung always abuts on the visceral pleura, infection excites an intense pleural reaction and adhesions form over the area of reaction. Since the greater part of the surface of the lung is in contact with the chest wall, in most cases these adhesions fix the site of the abscess to the chest wall. This does

not happen if the abscess reaches the pleura on the diaphragmatic or mediastinal surfaces of the lung, or in a fissure. In all other cases there is an area of adhesions through which the abscess can be drained without opening of the free pleural space. This area is sealed off early and the adhesions are firm within 2 or 3 weeks of the onset of the abscess. The area of fusion may be limited and is often not more than an inch or two in any direction; but with accurate localization it is usually adequate for approach to the abscess.

Cavitation always occurs in from 7 to 10 days from the onset, and in acute abscesses the cavity is found to average about 2 inches in diameter, and is solitary, spherical, and unilocular. It contains pus, debris, and sloughs, and after a few days opens into a bronchus; this allows the exit of the foul gases which cause the putrid smell and taste, even before any pus is evacuated. As the bronchial opening enlarges, pus and sloughs may be evacuated and spontaneous cure may result.

In most instances bronchial drainage is inadequate and the process tends to become subacute. Fibrosis develops in the wall of the abscess and in the adjacent lung, local extensions occur and cause multiloculation, and "spillover" into the adjacent bronchi results in satellite abscesses and bronchiectasis. At this stage drainage is useless, and the only hope of cure is by extirpation of the diseased portion of the lung. At any stage the abscess may perforate into the pleural cavity and produce a localized or generalized pyopneumothorax. Cerebral abscesses may result from blood spread, and amyloid disease may develop from long continued suppuration. "Spillover" into other parts of the lung may cause suppurative pneumonia or other abscesses. Acute, subacute, and chronic stages shade into one another; but it is helpful to separate them arbitrarily. For practical purposes an abscess less than 6 weeks old is acute; from 6 weeks to 3 months it may be considered subacute; and after 3 months it is considered chronic.

Symptoms are fairly constant. After operation there is usually an incubation period of a few days, followed by the onset of illness with flushes, chilliness, and rigors. Pain in the chest indicates the site of pleural involvement, and localized tenderness may be elicited over this area. A cough develops, and although at first it is dry, irritating, and nonproductive, in a short time—usually in 10 or 12 days from the onset—the patient begins to expectorate foul pus in increasing amounts. Some days before expectoration commences a foul odor may be noticed in the breath, and this is diagnostic of the presence of a lung abscess. Hemoptysis frequently occurs. The maximal interval between operation and onset is probably 14 days.

Prophylaxis includes carefully planned administration of an anesthetic. In operations of the mouth or throat in which it is likely that aspiration will occur, the anesthetic should be administered through an endotracheal tube and the pharynx should be packed or otherwise shut off. In any

operation, if aspiration does occur or is suspected, the air passages should be cleared at the end of operation by tracheal suction or bronchoscopy, and if atelectasis develops in the postoperative period, active measures should be taken to overcome it. The patient should be given morphine, laid on the sound side and vigorously thumped and rolled about. This may start a fit of coughing with the expulsion of a plug of mucus or blood clot, which will be followed by re-expansion of the collapsed area. If it fails, tracheal suction with a catheter may be tried or bronchoscopy may be used.

No operation of election should be performed in the presence of dental infection, and dental inspection should be a routine measure before operation in all hospitals.

Management of acute abscesses requires early surgical drainage in most instances, but once the condition of chronic pulmonary suppuration has been reached, although drainage may bring about some improvement, cure is rarely possible except by extirpation.

Probably 30 per cent of putrid abscesses resolve spontaneously and it is reasonable to be conservative for a few weeks in cases in which abscesses are apparently draining well into a bronchus, the course is not very acute, and the cavity is only moderate in size. Unless resolution is progressing satisfactorily, drainage should never be delayed beyond 6 weeks, and if symptoms recur after apparent resolution the abscess should be drained without further delay.

Sulfonamides are useless for putrid infections. Penicillin, however, is efficient in controlling them, provided drainage is adequate; but it is useless without effective drainage. STEPHEN A. ZIEMAN, M.D.

Evans, T. S., Swirsky, M. Y., and Chernoff, H. M.: Primary Endothelioma of the Pleura; Report of a Case in a Patient with Chronic Lymphatic Leucemia. *Ann. Int. Med.*, 1946, 24: 262.

This case report of a 40 year old white female from Grace Hospital, New Haven, Connecticut, concerns the association of a rare neoplasm and leucemia with a paucity of evidence of chronic lymphatic leucemia at autopsy. Whether this represents a spontaneous remission or an unusually prolonged favorable response to roentgen ray therapy is not clear. One may subscribe to the point of view that leucemias are neoplastic in origin and that the occurrence of a second primary neoplasm frequently inhibits the growth of the first one.

The literature on pleural endothelioma indicates that cases have been overlooked because symptoms suggest chronic inflammatory disease. Metastasis occurs late after the initial growth has become widely distributed over the contiguous pleural surfaces and there is no characteristic clinical or roentgenographic picture. Involvement of the pleural sac on the right side in males between the ages of 40 and 50 years is most common.

Physical examination of a patient with a fully developed clinical picture reveals dyspnea, orthopnea,

and sometimes cyanosis. The temperature is usually normal with an elevated pulse and respiratory rate. The chest findings are those of pleural effusion with shifting of the mediastinum to the contralateral side. Films taken after thoracentesis with air replacement of the fluid may reveal multiple tumor nodules on the surface of the pleura. Marked force is necessary to insert the needle into the pleural cavity. Fluid is frankly bloody or tends to become so on repeated taps and rapidly reaccumulates. An important differential point from tuberculous pleurisy is that dyspnea is not relieved by thoracentesis. Malignant cells are often reported on microscopic examination, but mesothelial cells can grow and multiply in such fluid.

The clinical course is that of advanced malignancy. Life expectancy is given as from 6 months to 2 years. Treatment is essentially palliative and the disease is invariably fatal.

At autopsy the lung is encased and compressed. The pleura is thickest at the base with a glistening sensation on transection. The inner surface of the pleura is finely nodular. The lung parenchyma is not involved. Metastasis involves the pericardium, the contralateral pleura, the diaphragm, and, in the peritoneal cavity, the mesentery near its intestinal attachment, the appendix, liver, spleen, kidneys, adrenal glands, and infrequently the ovaries and inguinal nodes. Axillary and cervical node involvement may occur. Ewing refers the origin of the tumor to cells of the subpleural lymph spaces or to the lining cells of the pleura.

The case reported is typical of pleural endothelioma clinically and pathologically. The patient's original complaint, however, was chronic exfoliative dermatitis with marked lymphocytosis showing lymphoblasts. Against the diagnosis of a primary skin disease with a leucemoid reaction is the fact that during the next few years the patient developed generalized adenopathy, splenomegaly, and the blood picture of chronic lymphatic leucemia, which was repeatedly confirmed. A leucemoid reaction to pleural endothelioma is unlikely since bone metastasis was not verified at autopsy and the blood picture preceded, by years, the onset of symptoms of a rapidly fatal intrathoracic malignancy. Also, the spleen showed a picture compatible with lymphatic leucemia during a remission and was without metastatic lesions. LANN JOHNSON, M.D.

HEART AND PERICARDIUM

Begg: Calcification of the Left Auricle. *N. Zealand M. J.*, 1945, 44: 315.

A case of calcification of the left auricle is described. It is the second case in which a roentgenographic record of the condition was made during life.

It appears that the primary lesion was a stenosis of the mitral valve, which led to chronic enlargement of the left auricle and subsequently to auricular fibrillation. Satisfactory compensation of the right heart enabled the patient to lead an active life with-

out any symptoms of cardiac origin. During this time, calcium was deposited in the walls of the dilated left auricle and in the mitral valve, as a degenerative change. As this occurred, mitral incompetence increased with consequent enlargement of the left ventricle. These gross changes had little effect on the patient until the right ventricle began to fail.

This type of endocardial calcification has not been reported as occurring in the right auricle or in either ventricle.

SAMUEL KAHN, M.D.

ESOPHAGUS AND MEDIASTINUM

Rafsky, H. A., and Herzlg, W.: Scleroderma with Esophageal Symptoms. *Gastroenterology*, 1946, 6: 35.

Ehrmann, in 1903, described esophageal disturbances in scleroderma, and several other authors have described cardiospasm, dysphagia, and esophageal changes in this condition. Changes in the small intestines have also been recorded. Five cases of this disease have been "esophagoscoped," and in 2, biopsies have been obtained.

The authors report 2 additional cases of scleroderma, in one of which a biopsy was taken esophagoscopically. This revealed only normal squamous epithelial cells, however. The microscopic changes described in the other biopsied case revealed "a fibrous membrane with or without mucosal destruction; the membrane was thick, containing fibrin, polymorphonuclear leucocytes, eosinophils and newly formed capillaries with large endothelial cells. The muscularis mucosa was invaded with polymorphonuclear leucocytes, eosinophils, and other inflammatory cells. The connective tissue was dense with some cells of a fibrocytic nature."

Scleroderma is recognized as the skin manifestation of a disease which affects several systems, including the skeletal, vascular, and gastrointestinal. One of the cases reported gave signs of circulatory impairment in the hands and feet; dysphagia appeared later on, and finally arthritic and skin changes were noted. The second case gave signs of circulatory impairment, then of dysphagia followed by arthritic manifestations, and finally there were skin changes. The early diagnosis of scleroderma may be difficult, until skin as well as other changes are present. One of the authors' diagnoses was confirmed by skin biopsy.

The case reports are given in some detail and illustrative roentgenograms are reproduced.

HIRAM T. LANGSTON, M. D.

Diaz, F., and Riera, M.: Esophageal Peptic Ulcer (La ulcera peptica del esofago). *Rev. méd. Chile*, 1945, 73: 1053.

Esophageal peptic ulcer was recognized by Albers in 1833. Its frequency as compared with gastric ulcer is about 1 to 30.

Generally, this ulcer occurs in the lower third of the esophagus. When it occurs higher it is usually due to causes other than peptic, such as pressure

around an inlying tube. The peptic ulcer is penetrating in type with well defined borders; an older one may be indurated and irregular. It heals by cicatrix. Esophageal spasm is frequently associated with this ulcer.

From the etiologic standpoint the following must be considered: (1) action of the gastric juice, be this by regurgitation, particularly if hyperchlorhydria exists, or by secretion from ectopic gastric mucosa; (2) any condition favoring dysfunction of the cardia and permitting regurgitation, such as pyloric stenosis, herniation of the stomach through the diaphragm, a short esophagus, or lower esophageal spasm; (3) some ill defined local lack of resistance to digestive action, perhaps related to a tendency to form thromboses or varices; (4) a "diathesis" in view of the association of esophageal with gastric and duodenal ulcers, and (5) esophagitis, although its relation to the condition is not clear.

Symptoms, when present, include: pain (in 84%) associated with swallowing, of variable intensity, retroxyphoid in location, and radiating sternally, to the neck, or to the shoulder region; dysphagia, which is frequent; and vomiting, especially regurgitation.

Complications include hemorrhage, perforation, and cicatricial stenosis or periesophageal adhesions.

The diagnosis is made by roentgenologic or endoscopic examination. One or both of these means in the order given may be required. The signs of this condition include: (1) spasm, (2) demonstrable defects, (3) a delayed passage of barium which is retained in the involved segment, (4) insufficiency of the sphincter of the cardia, (5) stenosis with proximal dilatation, and (6) dilatation of the lower third of the esophagus. The various subtypes of signs 1 and 2 are elaborated, and a discussion of the basic requirements for diagnosis regarding chronicity, the presence of free acid, and ectopic gastric mucosa is presented.

Seven case reports are given and their symptoms, and roentgenologic and endoscopic findings are analyzed. One case of associated esophageal cancer is included.

Thirty-three references to the literature are appended.

HIRAM T. LANGSTON, M.D.

MISCELLANEOUS

Betts, R. H., and Lees, W. M.: Military Thoracic Surgery in the Forward Area. *J. Thorac. Surg.*, 1946, 15: 44.

This report relates the experience of a thoracic surgical team of an auxiliary surgical group in Italy attached to the field or evacuation hospitals from December, 1943 to June, 1944. Circumstances required that this team care for casualties other than thoracic, although these were handled by preference. There were 192 patients treated, 164 of whom had thoracic injuries. There were 7 deaths, a mortality of 3.6 per cent. Many of the patients had associated injuries which were often more menacing than the thoracic injury.

In the preoperative preparation of the patients, disturbance of the cardiorespiratory physiology in addition to shock from the usual causes is very important. An airtight functional thoracic cage was generally managed in the Aid Stations. The clinical picture of shock may be produced by anoxia alone. Even relatively small amounts of air or blood in the pleura may, by their presence, aggravate a precarious general condition due to other factors. Aspiration of the pleura is, therefore, indicated. Excessive pulmonary secretions may reduce effective ventilation and should be relieved by coughing or intratracheal suction. Pain is best relieved by intercostal block.

Replacement of the blood which has been lost is necessary. One must be careful not to overload an already taxed circulatory system, particularly in blast injuries or excessively "wet lungs." Such cases may respond to serum albumin administration in such fashion that replacement therapy may be carried out. Oxygen is indicated for anoxia. The thoracic patient should be allowed to stabilize preoperatively, in contrast to the patient with wounds of the abdomen or extremities, in whom the avoidance of infection by immediate surgery is indicated. A thorough x-ray study is invaluable.

A competent anesthetist is indispensable. Intratracheal anesthesia is used for all penetrating and perforating wounds. Morphine was not given, since large doses had usually been administered previously; however, atropine was given. Local anesthesia was used for injuries of the chest wall only.

Surgical treatment was given to 82 lesions of the chest wall. The most troublesome involved the shoulder girdle and scapular region. Preservation of the upper third of the scapula is advantageous from the ultimate functional standpoint. Debridement should, however, be adequate. One fatal case of clostridium oedematis infection occurred.

Penetrating or perforating wounds are often referred to as "sucking wounds." This term is unfortunate and meaningless, since this characteristic depends upon the relation of the pleural opening to its extracostal coverings.

Since blood is uniformly present, aspiration is indicated. From 1,200 to 1,500 c.c. are sufficient for removal at one sitting. Air replacement is condemned. The lung is not a source of severe bleeding. In the absence of diaphragmatic perforation, intrapleural blood may be autotransfused. Attempts should be made to render the pleura dry.

Penetrating and perforating wounds may be divided into small (pleural defect less than 6 cm.) and large (pleural defect greater than 6 cm.) wounds.

Small wounds should be debrided or excised. When feasible, a catheter is inserted into the pleura and this is emptied. Irrigation with from 1,000 to 2,000 c.c. of saline solution is practiced. The wound is closed, except the skin, the pleura being aspirated through the catheter as the lung is inflated. The catheter is withdrawn as the last suture is tied. Attention is called to the careful removal of any

indriven rib fragments, particularly if they project from the chest wall. There were 49 cases in this group with no deaths.

Large wounds are considered traumatic thoracotomies. There were 14 cases with 2 deaths. This situation is considered an indication for thoracotomy. There were also cases of thoracoabdominal wounds, uncontrolled hemorrhage, large lung lacerations, and certain retained foreign bodies. Since many of these defects require tight closure, débridement should be as radical as is compatible with a stable chest wall. Closure of the chest wall often taxes the surgeon's ingenuity. Postoperative dressings should support the closure.

There were 19 cases of thoracoabdominal wounds. Seventeen were operated upon with 3 deaths, a mortality of 17.6 per cent (1 patient died preoperatively and 1 was transferred before operation). The surgical approach in these cases can be varied, but the upper abdomen can be adequately managed transdiaphragmatically, whereas the thoracic injury cannot be managed from below. A separate abdominal approach may be required for some lesions. The colon was exteriorized three times from above without infection. The diaphragm was repaired in two layers. Liver wounds should be packed and drained by subcostal stab wounds.

Severe bleeding most often comes from one of the systemic vessels, and a partially severed intercostal vessel was the only one seen at operation. No cardiac wounds as a cause for severe bleeding were treated. Intrathoracic metallic foreign bodies are removed if accessible easily. No major resection of the lung tissue was believed to be indicated in the lacerations seen. The thoracotomies were closed without drainage, but assiduous aspiration of fluid or air was practiced postoperatively.

The postoperative period is concerned with expansion of the lung and maintenance of a clear tracheobronchial tree. Attention is called to a possible noxious vasovagal reflex occurring during bronchoscopy, particularly at the end of general anesthesia. Atropine is considered a preventative. The urinary output is kept around 1,000 c.c. daily. Blood and plasma are given as indicated by laboratory studies. Pain is best relieved by paravertebral block. Oxygen is used freely.

Four illustrative case reports are appended, and provisions for the distribution of casualties so that they are accessible to skilled thoracic care are discussed.

Harken, D. E.: A Review of the Activities of the Thoracic Center for the III and IV Hospital Groups, 160th General Hospital European Theater of Operations from June 10, 1944, to January 1, 1945. *J. Thorac. Surg.*, 1946, 15, 31.

A chest center was established shortly before D Day in Normandy and a training period was begun for the assigned personnel. Four days after D Day the real work of the center began and 937 cases were treated. Five per cent of the casualties

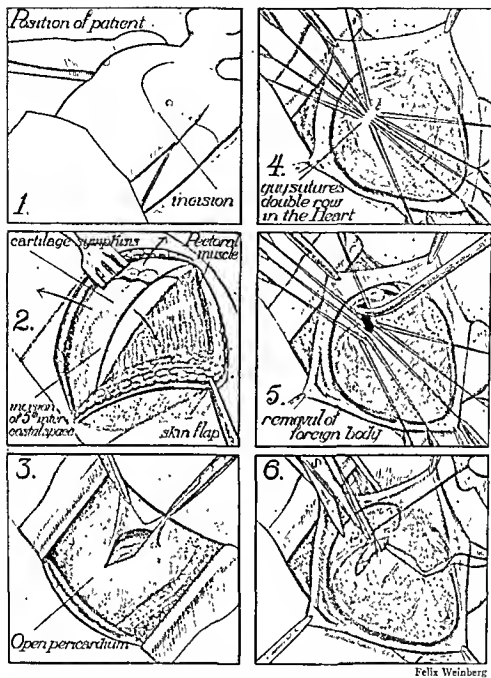

Fig. 1. Diagrammatic representations of the principles involved in the hemostatic removal of intracardiac foreign bodies, without interruption of the blood flow.

coming to the United Kingdom base section suffered major thoracic injuries. In the accompanying tables, the mortality shown for empyema was due to the associated injuries.

The principles in the treatment of various pathological conditions are discussed.

Hemothorax. The treatment in essence was complete aspiration and breathing exercises. The complications were (1) empyema, (2) reduced pulmonary function, (3) late pulmonary suppuration, and (4) deformity. Clotting occurred in approximately 10 per cent of the hemothoraces. Decortication was resorted to after about 2 weeks (in inspirable uninfected cases) if improvement from x-ray treatment

and breathing exercises was not adequate. Sixty-four cases were subjected to decortication. There were 48 contaminated multiloculated hemothoraces. Decortication without residual empyema was achieved in more than 75 per cent of them. When present, empyema was easily managed by open rib resection drainage. This complication was usually associated with a bronchopleural fistula. In a small number of cases decortication was performed for signs of acute cardiorespiratory embarrassment when relief by drainage or aspiration was impossible because of clotting.

In the infected cases, rib resection drainage was adequate for empyemas of 500 c.c. or less.

TABLE I. DISTRIBUTION OF PATIENTS WITH CHEST INJURIES ADMITTED TO GENERAL HOSPITALS IN THE UNITED KINGDOM BASE SECTION

Conditions	Percent- age	Percent- age	Percent- age
Hemothorax			70
Unclothed		60	
Infected	3		
Uninfected	57		
Clotted		10	
Infected	4		
Uninfected	6		
Retained foreign bodies			15
Requiring surgical removal		8	
Thoracoabdominal wounds			8
Hematoma of the lung			4
Injuries of the heart and pericardium			
Including retained foreign bodies			3
Twenty per cent of this group were referred to thoracic surgical centers.			

Empyema. Ninety-one resections were done for infected hemothorax or empyema. Policies in treatment involve: (1) early adequate drainage, (2) general and specific remedial exercises (including ambulatory treatment), (3) the maintenance of a state of acute inflammatory reaction in the cavity to prevent hyalinization and promote obliterative pleuritis (irritating packs are advocated for this), and (4) the maintenance of nutrition.

Thoracoabdominal wounds. There were 35 cases treated surgically. The empyemas were drained by rib resection, and associated subphrenic or liver abscesses were drained into the empyema transdiaphragmatically.

Removal of foreign body. The foreign bodies in the lung are removed if they are more than 1.5 cm. in two dimensions. Foreign bodies are generally removed to prevent hemorrhage and suppuration. Their removal is influenced by: (1) their size and irregularity, (2) their proximity to major vessels or the bronchi, and a dependent position in the parenchyma, and (3) the surrounding reaction. One hundred and sixty-two missiles were removed with no mortality. Eighty-five per cent of the missiles harbored culturable pathogenic bacteria, but only 2 empyemas resulted from 200 thoracotomies for removal of intrathoracic foreign bodies.

Cardiac foreign bodies are removed to (1) prevent embolism (by the foreign body or an associated thrombus), (2) reduce the danger of bacterial endocarditis, (3) prevent recurrent pericardial effusions, and (4) diminish the incidence of myocardial rupture or hernia. Thirty-two foreign bodies that were in or on the heart were removed, 9 were in the chambers. No deaths occurred. A composite diagram of foreign body location in these cases is given.

The steps in and modus operandi of the specified remedial exercises referred to originally are elaborated upon as a new therapeutic procedure adopted from the British. They lead to a return of function

TABLE II. DISTRIBUTION OF THE PRINCIPAL TYPES OF SURGICAL PROCEDURES, WITH 'MORTALITY RATES

Surgical Procedure	Number of Cases	Number of Deaths	Mortality Rate (Per Cent)
Removal of foreign bodies	247 ¹	1	0.4
Lung	162	0	0
Mediastinum	22	1	4.5
In or in relation to the heart	32	0	0
(chambers of heart)	9	0	0
In or in relation to great vessels	7	0	0
Diaphragm	10	0	0
Subphrenic area	14	0	0
Pleural space	31	0	0
Decortications	112	1	0.9
Uninfected clotted	64	0	0
Infected clotted	48	0	0
Thoracoabdominal operations	35	0	0
Liver abscess	11	0	0
Subphrenic abscess	10	0	0
Hepatobronchial fistula	8	0	0
Diaphragmatic hernia	6	0	0

to the long splinted, and therefore contracted, and variously immobilized thoracic cage or parts thereof. This effect is secured by the patient's acquiring the ability to voluntarily control motion in these various areas, which include the rib cage as well as the diaphragm.

HIRSH T. L. GOSWAMI, M.D.

Overholt, R. H., and Wilson, N. J.: Silent and Masquerading Intrathoracic Lesions. *N. Y. J. Med. J. M.*, 1946, 234: 169.

Mass surveys reveal three outstanding types of intrathoracic lesions: tuberculosis, carcinoma of the lung, and mediastinal tumors. The full value of survey work will not be realized unless a proper disposition of all the lesions is made in advance of the time when most of the patients ask for help because of symptoms. The potentialities of this type of preventive medicine are great.

Small tuberculous lesions with exudative or calcareous foci carry an immediate threat; but if they are fibrotic or calcified, inactivity must be demonstrated to guard the patients against long periods of unnecessary therapy, and to protect those with active lesions by prompt energetic treatment.

Any lesion shedding tubercle bacilli has some activity. Ninety-nine per cent of the patients with active tuberculosis are found to harbor tubercle bacilli by means of the concentration technique of pooled specimens and the study of gastric washing by multiple culture and guinea pig inoculation. The fundamentals of successful treatment of tuberculosis are early discovery of the lesion, and prompt, energetic, and prolonged treatment with bed rest, preferably in a sanatorium, and the judicious supplementary use of collapse measures.

Evidence points to the absolute and relative increase in incidence of bronchogenic carcinoma of the

lung occurring chiefly in males over 40 years of age. X-ray manifestations depend on (1) the type and location of the tumor, (2) the degree of bronchial occlusion, (3) whether infection in the parenchyma has taken place, and (4) whether mediastinal or chest wall extension has taken place. X-ray findings may be indistinguishable from tuberculosis, bronchiectasis, unresolved pneumonia, or suppurative disease. If the lesion is caused by carcinoma, speed in diagnosis and surgical extirpation offer the only chance for cure.

Diagnostic procedures include: (1) search for peripheral metastasis for biopsy, (2) bronchoscopy, about 50 per cent efficient in securing tissue for examination, (3) lipiodol bronchography, (4) study of the sputum for malignant tissue, usually disappointing, (5) aspiration biopsy, and (6) exploratory thoracotomy, which is as safe and accurate as abdominal exploration to determine the diagnosis and operability. Following the examination of a frozen section, surgery can be carried out immediately.

Mass surveys show that mediastinal tumors are much more frequent than has been suspected from

previous clinical and autopsy data. Localization is important in determining the type. Most frequent in the posterior mediastinum are ganglioneuromas and neurofibromas, while in the anterior mediastinum dermoid cysts, teratomas, malignant lymphomas—lymphosarcoma Hodgkin's disease, and leucemic lymphoma—are most frequent.

Surgical extirpation is indicated in benign tumors, with rare exceptions. Benign tumors grow slowly and are usually oval or circular, quite dense, and sharply delimited. Malignant tumors grow rapidly, and tend to be lobulated and less sharply defined. Cervical or axillary nodes are frequently associated with malignant lymphomas and should be biopsied. Dermoids and teratomas may reveal teeth or bones in heavy exposure roentgenograms with a Potter-Bucky diaphragm. Fluoroscopy and roentgen kymography assist in ruling out aneurysm. In anterior mediastinal tumors a therapeutic test dose of x-rays is advised. If the tumor fails to respond within from 4 to 6 weeks, surgical exploration is indicated without delay to avoid technical difficulties resulting from the effects of the x-rays on local tissue.

LYNN JOHNSON, M. D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Turnbull, H.: Inguinal Hernia and Its Repair. *Med. J. Australia*, 1946, 1: 109.

The Bassini operation is standing its trial. English surgery in particular has been vehement in its condemnation, and unequivocally demands the death of the Bassini technique.

Turnbull makes a plea for the retention in surgery of the Bassini operation. He presents the criticisms of the operation and endeavors to answer them in order.

1. Statistics of recurrences must always be suspect, and cases are presented to illustrate how treacherous and misleading figures without detail can be.

2. Ogilvie's arguments that (1) suturing the conjoined tendon to the inguinal ligament means a muscle working out of place, (2) the abdominal wall is weakened, and (3) recurrence is favored rather than prevented, are answered in discussing the anatomy of the inguinal region.

In giving the causes of recurrences, it is stated that all indirect hernias are congenital, and Nature has fallen down on her job; that it is thus beyond our means to prevent the occurrence of hernia, but by adequate operation planned on physiological and anatomic grounds, the condition can usually be cured and recurrences largely prevented. The causes of recurrence in most cases can be labelled as bad surgery due to ignorance of the condition, and are discussed under headings of poor technique, ill advised operation, faulty preoperative supervision, faulty suture material, and postoperative complications.

The author believes that there are only two hernia operations that should ever be performed: (1) simple excision of the sac with tightening of the transversalis fascia; (2) a modified Bassini repair, alone, or combined with a fascial graft. In his opinion, all other operations are superfluous. His technique of the modified Bassini repair is presented in detail.

After disposing of the sac by high suturing and amputation, the incised fascia is united with a few interrupted silk sutures cut directly on the knot, and the under surface of the conjoined tendon is completely freed from the transversalis fascia until it can be grasped as a separate entity. The transversalis fascia is tightened and strengthened. This is done either by a purse-string suture or by interrupted silk sutures. The internal ring is now narrowed by interrupted sutures placed on the inferomedial surface until the ring is comfortably tight and admits only the tip of the finger. The neighboring lateral border of the rectus sheath, the area of the linea semilunaris, is sutured to the periosteum of the pubic tubercle. The needle must be felt to bite in and the suture grip hard. This is the most important stitch in the whole

repair. It fixes the most medial point of the conjoined tendon and relaxes the rest of the tendon, enabling it to be sutured to the inguinal ligament without tension.

Vertical mattress sutures of silk are then used for the repair. The fibers of the inguinal ligament run longitudinally, so that the sutures must not be inserted parallel to the fibers, but across them; otherwise they will tear out, split, mutilate and weaken the ligament, and thus weaken the repair. The second important point in the application of these sutures is that they must be tied on the distal surface of the inguinal ligament—that is, on the femoral triangle side. The conjoined tendon is stitched to the inguinal ligament by interrupted sutures until it fits snugly under the cord emerging from the internal ring. One or two sutures are now inserted above the cord, uniting the internal oblique to the inguinal ligament. This is an important step in strengthening the internal ring, for the repair is now firm all around the emerging cord.

The external oblique is repaired with interrupted "figure of eight" sutures. The external oblique may be redundant. If so, it is overlapped after the method of Mayo. If it is considered necessary to further strengthen the repair, fascial strips from the external oblique should be plaited into the repair.

Except for the method of dealing with the sac, the operation of repair for direct hernia is the same as the modified Bassini operation described.

STEPHEN A. ZIEGLER, M.D.

Fisher, H. C.: Postappendectomy Interstitial Inguinal Hernia. *Ann Surg*, 1946, 123: 419.

An unusual type of hernia was encountered in 8 of 369 cases of right inguinal herniorrhaphies. The patients had had an appendectomy from 4 to 27 years previously. They presented the typical findings of a right inguinal hernia with a reducible, bulging mass at the external inguinal ring which descended with increased intraperitoneal pressure. The findings at operation were in contrast to those of the usual inguinal hernia, however. No sac of the peritoneum could be found in the inguinal canal. Instead, an omental mass was present which coursed beneath the transversus abdominis and internal oblique muscles to pass through a peritoneal defect at the original McBurney incision. To explore this region adequately it was necessary to open the peritoneal cavity. In only 2 case of the 8 was an associated inguinal hernia (indirect) discovered. This type of hernia was described in 1911 by Hoguet.

In this series a modified Bassini procedure was used and the patients were allowed to be active after 14 days of bed rest. No recurrences were observed in a period of from 3 months to 3 years.

This hernia occurs in the presence of poorly closed or drained, or infected appendical wounds. The

Fig. 1. Diagram illustrating the dissection of the omentum from the parietal peritoneum in the region of the defect. (Courtesy of J. B. Lippincott Co.)

necessity for careful exploration of the inguinal region by opening the peritoneal cavity is stressed.
C. FREDERICK KITTLE, M.D.

during the noon instead of the evening meal. Conservatism is advised when surgery is considered or is undertaken for duodenal ulcer in man.

WALTER H. NADLER, M.D.

GASTROINTESTINAL TRACT

Sandweiss, O. J., Sugarman, M. H., Podolsky, H. M., and Friedman, M. H. F.: Nocturnal Gastric Secretion. *J. Am. M. Ass.*, 1946, 130: 258.

On the basis of 150 nocturnal gastric secretion studies performed on 38 normal persons (73 studies) and on 29 patients with duodenal ulcer (77 studies), the authors report the following impressions:

Both normal individuals and patients with duodenal ulcer secrete acid gastric juice during the night even when the evening meal consists of foods usually allowed ulcer patients. After a fairly well balanced meal at 6:00 P.M., the hydrochloric acid concentration is approximately the same in both groups, and following this meal the nocturnal volume of gastric juice obtained by continuous suction is on the average not greater in ulcer patients than in normal persons. However, when intermittent single aspirations are performed during the night a greater quantity of gastric juice is found in ulcer patients than in normal subjects of the same sex, probably because of a state of delayed gastric emptying. Only 1 of the ulcer patients studied seemed to have a tendency toward gastric hypersecretion.

The authors point out that if hydrochloric acid is the chief factor in ulcer distress and delayed healing, more attention must be paid to the nocturnal phase of gastric secretion even though no symptoms are present. Feedings during the night are, therefore, essential. When meat and fish are added to the diet of ulcer patients it is advisable to include them

during the noon instead of the evening meal. Conservatism is advised when surgery is considered or is undertaken for duodenal ulcer in man.

WALTER H. NADLER, M.D.

Valle, A. R., and White, M. L., Jr.: Thoracic Gastric Cyst. *Ann Surg.*, 1946, 123: 377.

There is a great variety of cysts which occur in the mediastinum. One of the more unusual types is of endodermal origin—the gastric cyst. There are two kinds of gastric cysts, those that are acid secreting or functionally active, and those of which the mucosa is without functional activity. Even though the acidity of the cystic secretions was not determined in the reported case, the early manifestation of symptoms (primarily hemorrhage) is so typical of the proved functionally active cases in the literature that the authors believed they were justified in classifying this case as an acid secreting or functionally active cyst. From a review of the literature it is found that there are two constant characteristics of a gastric cyst—it always occurs in the posterior mediastinum and always on the right side. The functionally active cysts usually manifest themselves by symptoms at an early age, whereas the inactive ones may be discovered accidentally in a routine chest roentgenogram later in life.

There are several theories about the origin of endothoracic gastric cysts. They have been ascribed to a pinching off of an evagination of the embryonic foregut, to an intrathoracic vestige of the omphalo-mesenteric duct, and to a proliferation of endodermal germ cells of the esophagus capable of producing gastric epithelium.

The cyst wall has all the elements of the stomach wall. Smith and Stachelin-Burckhardt have each reported a case which exhibited both gastric mucosa

Fig. 1. Bronchogram showing cyst communicating with the right lower lobe bronchus. Arrows outline the cyst which is partially filled with iodized oil.

and ciliated stratified respiratory epithelium in the same cyst. Boss has described a case in which the intrinsic nerves and ganglia of the gastric musculature were identified.

In the case reported by the authors, the cyst perforated the diaphragm and terminated in a blind sac about 5 cm. below it. This feature has not been reported in the literature. The cyst did not communicate with the stomach or the esophagus. Erosion of bone may be caused by the cyst as was reported by Mixer and Clifford as occurring in one of their cases.

The most commonly observed symptoms of gastric cyst are dyspnea, cyanosis, cough, dysphagia, and, sometimes, even in infants, hemoptysis. The most striking symptom in the authors' case was the massive hemoptysis which necessitated admission to the local hospital on 9 different occasions, with multiple blood transfusions during each period. Both Boss and Seydl reported hemoptysis in their cases and attributed it to the presence of chronic peptic ulcers in the gastric cyst. In both cases the ulcers penetrated into the adjacent lung and caused fatal pulmonary hemorrhage. Although no peptic ulcer could be demonstrated in the specimen from the authors' case, it is probable that one had been present, since the cyst had eroded into the right lower lobe bronchus and was draining through the bron-

chial tree. Inasmuch as this cyst was functionally active, the hemoptysis was probably due to bleeding from the ulcer itself and to the action of the gastric juice on the parenchyma of the lung and the bronchial tree.

The physical findings are variable but are usually those of pulmonary atelectasis or pneumonia. There may be some cardiac displacement, scoliosis, or, rarely, bulging of the chest. The findings in this case were primarily those of severe pneumonia. The generalized bronchiectasis of the right lung, a complication resulting from the rupture of the cyst into the bronchial tree, has not been previously reported.

It is difficult to diagnose a gastric cyst during life with any degree of certainty without exploratory operation. However, the diagnosis is possible if gastric juice is aspirated directly from the cyst. The cyst may contain from a few cubic centimeters to 400 c.c. of fluid. The reaction is usually acid but may be neutral. Roentgenograms in both the postero-anterior and lateral projections are important, but the lateral view is particularly so, as it shows the cyst in the posterior mediastinum. Iodized oil cyst in the posterior mediastinum. Iodized oil bronchography is of use to show whether or not the cyst communicates with the bronchial tree and, if it does, to demonstrate its size, shape, and location. In this case a diagnosis of posterior mediastinal cyst

Fig. 2. Photomicrograph showing typical gastric mucosa and bronchial cartilage (Courtesy of J. D. Lippincott Co.)

communicating with the bronchus, complicated by generalized bronchiectasis of the right lung, was made preoperatively. However, it was not until the typical gastric mucosa was seen when the cyst was opened during operation that the correct diagnosis was suspected.

The only treatment for gastric cysts is complete removal. If only a minute amount of the mucosa remains in the chest it will secrete and cause further complications such as empyema or a draining sinus, with or without excoriation of the skin. To date surgical treatment has not been too successful. Of the 17 cases summarized, 10 were given surgical treatment. Five of the patients survived, which represents an operative mortality of 50 per cent. Two of these had a successful two-stage operation (drainage and later excision), and 3 had a one-stage removal.

The high mortality is quite probably due to several factors: the patients are usually infants; they are usually in poor condition for a major operation; it is difficult to administer anesthesia; and the dissection of the cyst from the mediastinum is technically impossible in some cases. The last factor is due probably to adjacent inflammatory reaction from the functional activity of the cyst. In some cases in which complete removal of the cyst is impossible in a one-stage operation, preliminary drainage is useful as a palliative measure.

CHARLES BARON, M.D.

Koster, K. H., and Trolle, D.: Investigations of Postoperative Shock: Hemoconcentration, Plasma Protein, and Blood Electrolytes after Gastrectomy. *Acta chir. scand.*, 1946, 93: 51.

The authors believe that it is profitable to study the lessons of shock in civilian surgery. It can be studied in closer detail than under war conditions.

The circulation is severely taxed after any major abdominal operation, as the blood volume is reduced. Often this strain is easily overcome, but if it exceeds the body's compensatory powers, the insufficient circulation will dominate the clinical picture. Post-operative alterations in circulation are due to the reduction in blood volume from the loss of blood, loss of plasma into the tissues, and a high degree of dehydration. Blood pressure falls are due to sympathetic stimulation from manipulation of the viscera, and anesthetization of the splanchnic area. The reduced blood volume leads to falling venous pressure, diminished diastolic filling, and reduced cardiac output, with increased rate and diminished stroke volume. To preserve blood for the carotids and coronary system, the peripheral vessels contract. The relative anoxemia of the capillaries which develops causes an increased plasma loss. This vicious cycle continues until the shock picture becomes manifest.

The fate of the patient depends on his ability to re-establish and maintain a normal blood volume with adequate cardiac output, circulation, and an adequate supply of oxygen to vital centers; and infusions of saline and blood are given to assist the body. It is not possible to recognize clinically an incipient reduction in blood volume—latent shock. As treatment should be instituted in this phase, variations in the blood volume during the post-operative period must be started.

Frequent blood volume determinations are impractical, so other methods of study are needed. Red cell counts and plasma protein determinations have been chosen as guides to variations in blood volume and water content of the body. Observation of the bicarbonate and chloride content of the blood will be helpful in studying the patient's total fluid balance.

The authors present an extensive study of 63 patients who underwent gastric surgery during the period from January, 1930 to July, 1943. Of these, 26 were operated upon for gastric ulcer and 37 for gastric carcinoma. Billroth II gastroenterostomies were done in all but 4 cases in which total gastrectomies (2) and Polya anastomoses (2) were done. Splanchnic anesthesia with novocaine, supplemented by local and nitrous oxide oxygen ether narcosis while closing the wound was used in every case.

Postoperatively, a duodenal tube was inserted in the efferent loop of the gastroenterostomy. Blood transfusions were widely used. Vasopressin to counteract paralytic ileus, vitamins, and sulfathiazole both interperitoneally and systemically, were given; 2,400 c.c. of fluid daily were taken through the tube, which was left in 8 days, if possible. When necessary,

supplementary infusions were given subcutaneously or intravenously.

Hemoconcentration is a guide to changes in the blood volume. Such changes in hemorrhage occur—and consist of dilution which is an indication of the body's attempt to maintain normal blood pressure. This occurs both in shock, when concentration shows a plasma loss from the circulating blood, and in dehydration, when the reduced blood volume indicates drainage of the extracellular water reservoirs.

In shock with hemorrhage, compensation occurs by vasoconstriction which reduces the capacity of the vascular bed, and by the inflow of tissue fluid. Restoration of blood volume begins soon after hemorrhage, and takes place rapidly. After a loss of from 15 to 20 per cent of the blood volume, the circulating volume is restored in a period of 3 hours. At this time the plasma volume is greater than before, and corresponds to a reduced cell volume. Provided sufficient fluid is available, a fall in the red cell count and plasma protein levels can be detected only a few hours after hemorrhage.

In shock without hemorrhage, there is a reduced blood volume and an increasing hemoconcentration due to plasma loss through more permeable capillaries. It is important to realize how great this plasma loss may be. A plasma volume reduction of 2,100 c.c. was found in a case of burns involving 12 per cent of the body surface.

Plasma constantly supplies fluid to secretions and insensible perspiration, and receives fluid from the intestines and available extracellular water (15 to 20 liters in an adult man). It is believed that this reservoir must be greatly reduced before a diminished plasma volume and an increased hemoconcentration occurs. It is obviously impossible to calculate the degree of fluid deficiency from the hemoconcentration.

In a long operation, with much bleeding and handling of viscera, two rival processes are initiated: (1) following bleeding, fluid moves from the tissues into the vessels, which decreases the hemoconcentration; (2) loss of plasma in the operative field and, eventually, in the peripheral areas, tends to increase the hemoconcentration. During the first few hours either process may predominate.

An account is given of pre- and postoperative investigations of hemoconcentration, plasma protein, plasma bicarbonate, and plasma chloride concentrations, and of the fluid balance of 61 patients who underwent gastrectomy.

A fall in hemoconcentration was observed in the patients who survived operation, the greatest fall occurring in those whose condition was best. In these patients, the dilution of blood was rapid and marked, which indicated an effective restoration of blood volume following the loss of blood during the operation.

In 12 patients, the hemoconcentration after operation was 25 per cent higher than before operation. All died, in spite of the fact that the hemoconcentration was successfully reduced to normal. An increase

of 25 per cent in hemoconcentration corresponds to a reduction of blood volume to 20 per cent. When the blood volume falls below this point, irreparable injury to the central nervous system occurs.

The authors were unable to demonstrate a rise in hemoconcentration as the result of blood transfusion.

The determination of plasma protein by measuring the specific weight of the plasma (without knowledge of the albumin-globulin ratio) is not reliable with respect to its colloid osmotic pressure. For this reason, and others, it is unreliable to depend on the edema limit—5.5 per cent protein in the plasma—when administering infusions of crystalloids.

Although 11 cases showed pulmonary edema at autopsy, all had had a plasma protein concentration of higher than 5.5 per cent.

No pronounced case of acidosis occurred in these series.

Plasma chloride concentration is discussed. It is emphasized that this factor cannot be an expression of the fluid demand of the organism and that one cannot administer fluid on the basis of these figures.

ROBERT R. BIGELOW, M.D.

Wangensteen, O. H.: The Ulcer Problem. *J. Lancet*, 1946, 66: 31

Two phases of the ulcer problem are discussed: (1) etiology, with special reference to the interrelationship between the vascular and acid-peptic digestive factor in the genesis of ulcer; (2) characterization of a satisfactory operation which will protect against recurrent ulcer.

The daily implantation of 30 mgm. of histamine base in beeswax and mineral oil was used as the method of ulcer production, and varied surgical procedures were then used to evaluate their capacity to prevent ulcer.

r. Four patients with fractures had either hematemesis or melena. A diagnosis of peptic ulcer was made, and it was concluded that fat emboli following fracture led to vascular obstruction and predisposed to peptic ulcer. This conclusion was substantiated by the appearance of ulcer in rabbits following the intravenous injection of fat plus the histamine base injection. Moreover, 3 rabbits injected with fat but given no histamine did not develop ulcer; and 2 rabbits given histamine alone also failed to develop ulcer.

An attempt was next made to produce chronic vasomotor arterial spasm by epinephrine injection. Previous studies had shown that it is difficult to produce ulcers in rabbits by the injection of histamine beeswax alone, but in the author's experiments on 4 rabbits, in which epinephrine was added to the histamine base, ulcer or erosion occurred in each instance. The possible role of pitressin in ulcer was also considered. Again, the conclusion was drawn that chronic arterial spasm invoked by epinephrine or pitressin produces local areas of anemia in the gastric mucosa. These areas then become susceptible to the acid-peptic digestive activity of the gastric juice.

If it appears safe to conclude that arterial spasm of gastric end vessels invites erosion of the gastric mucosa, why should not mucosal congestion secondary to venous stasis lead to the same result? In a study on rabbits and dogs, the venous flow from the stomach was partially obstructed. The results of the experiments showed that obstruction of the venous drainage from the stomach abets the ulcer diathesis. Erosion and ulcer were far more readily provoked when the histamine injection occurred in the presence of portal hypertension than when there was no obstruction of the venous outflow of the blood from the stomach. These conclusions were confirmed in a small series of patients having portal hypertension caused by cirrhosis of the liver or thrombophlebitis of the portal and/or splenic vein. Four out of 5 of these patients were cured of the gastrointestinal bleeding by an extensive gastric resection.

2. In the characterization of a satisfactory operation for ulcer, the problem was subjected to experimental scrutiny as follows: Three series of experiments were carried out on dogs. In each series a three-quarters gastric resection, including excision of the pylorus and antrum, was done. The only variable was the length of the proximal afferent duodenojejunal loop. The operation was the Hofmeister modification of the Billroth II resection. In series I, following extensive gastric resection, the gastrojejunostomy was performed as close to the inverted duodenal end as was technically possible. After a period of 3 months, the histamine beeswax was injected daily for from 40 to 45 days. None of these animals exhibited an ulcer.

In series II the same procedure was followed, with the exception that the afferent duodenojejunal loop was longer, now being 27 to 78 cm. as contrasted to the 13 cm. in the first series. A similar 3 months postoperative period was adopted; then the histamine base was injected daily. Gastrojejunal ulcer occurred in 100 per cent of this group of animals.

In series III the afferent duodenojejunal loop was 78 to 144 cm. The animals received no histamine. Fifty per cent of them died of spontaneous perforation of the gastrojejunal ulcer. The other 2 exhibited no pathology. From this study has evolved evidence indicating that a long afferent duodenojejunal loop invites stomal ulcer.

In the next experiment, an attempt was made to ascertain whether a less extensive gastric resection would protect against the histamine provoked ulcer if a Billroth I type of operation were done. In 3 series of dogs, the following results were obtained. After a 25 per cent gastric resection, 75 per cent of the animals developed stomal ulcer. When 50 per cent of the stomach was resected, again 75 per cent of the animals developed stomal ulcer, but when 75 per cent of the stomach was removed, stomal ulcer did not occur.

The success following a 74 per cent gastric resection with a short afferent duodenojejunal loop suggests that a satisfactory operation has been found.

SAMUEL J. FOGELSON, M.D.

Winkelstein, A.: The Prophylaxis of Peptic Ulcer. *Gastroenterology*, 1945, 5: 457.

The prevention of the peptic ulcer involves three separate problems: (1) the prevention of peptic ulcer in general, as a community problem; (2) the prevention of peptic ulcer in the individual; and (3) the prevention of peptic ulcer recurrences in the individual patient. These three problems naturally overlap.

The first of these factors requires the consideration and prevention of neurosis in adult life, often the result of psychic traumas in childhood. The dietetic habits of the American people should be improved; the excessive use of coffee, condiments, charged water, fried foods, and large amounts of fat, leads to gastric hypersecretion and spasm with primary and secondary inflammatory reactions. The injurious role of tobacco and alcohol in the problem of peptic ulcer should be given most serious consideration. There is also a high familial incidence of peptic ulcer. Julius Bauer, of Vienna, has shown that there are families in whom there is a strong tendency to acquire ulcer, "given the suitable exogenous aggressive factors." George Draper has reached similar conclusions from anatomic data.

In considering the prevention of peptic ulcers in an individual the above factors, as they apply to the ulcer type of patients, should be observed. The individual who has the "lean and hungry look of Cassius or the outspoken 'ulcus facies'" should be warned to avoid gastric irritants in so far as is possible. These individuals are characterized by an increase of interdigestive acid secretion which is present in ulcer patients and absent in the normal stomachs. When this gastric hypersecretion is absent during the night, the individual may be stamped as an ulcer candidate, and should be taught to avoid, or at least diminish, exposure to exogenous gastric irritants.

The prophylaxis of recurrences in the individual ulcer patient requires the serious consideration of (1) dietetic errors; (2) alcohol and tobacco; (3) emotional factors; (4) physical and mental fatigue; (5) seasonal or periodic recurrence, i.e., in the spring and in the fall; (6) infections (chiefly upper respiratory); (7) reflex causes (diseases elsewhere in the body, especially in the abdomen). The elimination of all such factors should be part of a prophylaxis effort.

Patients with ulcer should go on ulcer therapy during periods of physical and mental fatigue, in the spring and in the fall, during and after upper respiratory infections, after surgical procedures elsewhere in the body, and possibly regularly 1 day each week, and for 2 weeks every few months.

At the present time, the prevention of peptic ulcer as a military problem should be considered. In two large American Army hospitals, an average of 34 per cent of the patients with gastrointestinal ailments had ulcers. It was significant that approximately 80 per cent of the patients had ulcer symptoms previous to Army life. For this reason the conclusion

is drawn that men with a definite history of peptic ulcer should not be accepted for military duty.

SAMUEL J. FOGELSON, M.D.

Moses, William R.: Acute Obstruction of the Small Intestine. *N. England J. M.*, 1946, 234: 78.

One hundred and eighteen cases of acute, complete small bowel obstruction seen in a large municipal hospital are presented. Of the 118 patients treated, 10 died, a mortality rate of 8 per cent. The low mortality rate is attributed to the careful assessment of the general condition of the obstructed patient before any operative procedure is attempted rather than to emphasis upon the local disease. The method of treating acute obstruction of the small bowel is to provide surgical correction of the condition when the patient has reached the peak of general systemic improvement.

The number of patients seeking early municipal institutional care that would permit immediate surgery is small. However, in such a group of patients a prophylactic treatment is recommended for shock, intubation, suction, and blood or plasma before and during operation, despite their satisfactory condition on admittance. The larger group of patients demand an exhaustive study to assess the ability to withstand any contemplated operation. The author favors postponing surgery in this latter group until: the pulse is stabilized below 120; the blood pressure is at normal or near normal limits; the acid base balance is restored (as estimated by the type of respiration, the plasma carbon dioxide combining power, acetoneuria, determination of serum sodium and chloride levels, and so forth); hydration has been achieved (as determined by the feel and appearance of the tongue, blood urea nitrogen studies, the specific gravity and quantity of urine passed during preparation and hematocrit studies); the definite treatment of complications, such as pneumonia and heart failure, is well under way; there is significant improvement in distention, and the general effects of shock (sweating, pallor or cyanosis, coldness of the extremities, and mental torpor or severe anxiety) have been alleviated.

JOHN E. KARABIN, M.D.

Wood, W. Q.: The Treatment of Duodenal Ulcer. *Edinburgh M. J.*, 1945, 52: 433.

The problem of peptic ulcer has become increasingly important. It is not only a very common disease, but it has shown a steady increase in frequency as determined by the steady rise in mortality. In England and Wales, there were 43,000 deaths in the 10 years before the war, as a result of peptic ulcer. The number of men discharged from the Army up to December, 1941 (a little over two years) because of peptic ulcer was 23,574. Approximately 200,000 new cases in males each year are estimated to occur in England and Wales alone. Moreover, the frequency of perforation, observed in the hospitals of the West of Scotland, has more than doubled in the period between 1924 and 1941.

The etiology of duodenal ulcer is discussed, and emphasis is placed on the role of mental and psychophysiological strain. During the worst period of air bombardment in London, a marked rise was noted in the number of cases of perforated ulcer.

The methods of treatment have passed through several phases during the past 20 years. Specific decisions have been reached, which may be grouped into four points of view.

1. The treatment of the uncomplicated duodenal ulcer is a medical (not a surgical) problem.

2. Gastroenterostomy, in the absence of well marked organic stenosis, is a bad operation and is universally condemned.

3. In the presence of well marked stenosis, gastroenterostomy is a safe procedure and gives good results.

4. In patients with duodenal ulcer without stenosis, in whom operative treatment is indicated, an extensive partial gastrectomy (subtotal gastrectomy) is the only justifiable procedure.

Following the conclusion that subtotal gastrectomy is essentially a satisfactory procedure, alternative surgical procedures are considered, as follows: Gastroenterostomy again, but only under specific conditions; operations at the pylorus, such as pyloroplasty; gastroduodenostomy, which is condemned; partial gastric exclusion, as suggested by Devine, which is also found to be an unsatisfactory procedure; partial fundusectomy, as suggested by Connell, which has not been done sufficiently to warrant conclusions; vagotomy, which still requires further evaluation, and, finally, ligation of the gastric blood vessels which, in a limited series, was reasonably satisfactory. SAMUEL J. FOGELSON, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

With, T. K.: The Bilirubin Production of the Human Organism and Its Significance in the Pathogenesis of Jaundice. *Acta med. scand.*, 1946, 123: 166.

That there is considerable individual variation in the production of bilirubin by the human organism has been shown by the author, who used several methods independent of each other.

Of 3 methods of determining bilirubin production, the most accurate is that of collecting the 24 hour output of bile and determining its bilirubin content. This was done on 35 cholecystectomized patients who had drains in their common ducts. About 7 days after operation the final constant level of bilirubin production was reached; it was found to be from 50 to 400 mgm. per 24 hours, and in most cases between 50 and 250 mgm.

The second method measures the bilirubin production in terms of the urobilinoid excretion with the feces. Since urobilinoids may be absorbed or destroyed in the intestine, this measure is only a rough correlation and, at best, represents only a lower limiting value for bilirubin production.

The third method is the determination of the excreted amount of urobilinoid plus bilirubin in the urine and feces in cases of jaundice. If there is not a complete biliary obstruction, this method is subject to the same error as the second method insofar as fecal urobilinoids are concerned. The error is eliminated if biliary obstruction is complete. However, variations in the bilirubin content of various depots in the body—the serum, the tissue fluids, the tissues themselves—prevent excretion from being an accurate index of production. In 5 patients who had subsequently proven complete biliary obstruction, the bilirubin excretion in the urine was 20 to 50 mgm. per 24 hours. This low figure may mean that production is actually lowered, or it may mean that the bilirubin is largely broken down before it can be excreted.

In cases of complete biliary obstruction, the severity of the jaundice (the serum bilirubin concentration) is influenced by bilirubin production and by the ability of the kidneys to excrete the bilirubin. As shown in the 5 cases mentioned, this renal excretory power is low; hence, the severity of the jaundice in complete biliary occlusion is largely a function of the bilirubin production.

One factor in the metabolism of hemoglobin which probably has not received proper consideration is that much of the hematin of hemoglobin may give rise to bilifuscin and mesobilifuscin. Abnormally low bilirubin production resulting from this mechanism may explain some puzzling but unquestionably authentic cases of complete biliary obstruction and acute yellow atrophy of the liver in which there was no jaundice.

J. F. LOUNSBURY, M.D.

Shallow, T. A., Eger, S. A., and Wagner, F. B., Jr. Congenital Cystic Dilatation of the Common Bile Duct. *Ann. Surg.*, 1946, 123: 159.

There have been 182 cases of congenital cystic dilatation of the common bile duct reported in the literature, including the authors' case. The first case reported by the authors is a follow-up of a patient operated upon in 1941. The dilated common duct was removed and the right and left bile ducts were separately anastomosed to the duodenum. A follow-up almost 4 years later revealed the patient to be in excellent health. The bromsulphalein liver function test was normal and the Van den Bergh reaction was negative with a serum bilirubin of 1.0 mgm.

The second case was that of a 58 year old white woman. During the year prior to her admission she noticed her abdomen was gradually and persistently increasing in size. There was no discomfort or pain. Periodically her urine was darker than usual and her stools light in color. No jaundice was noticed. The abdomen was distended similar to an 8 month pregnancy but the tumor mass appeared to originate in the upper abdomen. The mass was mobile. The bromsulphalein liver function test showed 40 per cent dye retention. The Van den Bergh reaction was directly positive with a serum bilirubin of 2.0 mgm. The prothrombin time was within the normal.

Fig. 1. Roentgenological studies in Case 1, in which the cyst was excised. Arrow in (A) shows displaced stomach and duodenum preoperatively. (Courtesy of J. B. Lippincott Co.)

Roentgen examination of the gastrointestinal tract revealed the stomach and duodenum to be markedly pushed to the left. The hepatic flexure of the colon was displaced downward to the level of the brim of the pelvis. The cholecystogram was indefinite; no stones were seen.

At operation the common duct was hugely dilated and the gall bladder was normal. From the cystic mass 5,800 c.c. of thin, dark brown material was obtained, which was later shown to contain bile and a moderate amount of amylase. An anastomosis was made between the cyst and the duodenum.

Recovery was uneventful and 7 months later there was no abdominal swelling, jaundice, or pain. The stomach, duodenum, and colon were shown by x-rays, to be in normal position. There was 5 per cent dye retention following the bromsulphalein test and the Van den Bergh test was negative.

The authors state that the cyst should be removed only if it is small and the patient's condition is good. Anastomosis of the cyst to the duodenum is usually the preferable procedure.

EARL O. LATIMER, M.D.

Scott, H. W., Jr., and Bowman, J. R.: Traumatic Rupture of the Spleen. *J. Am. M. Ass.*, 1946, 130: 270.

Seven cases of traumatic rupture of the spleen were seen on the surgical service of the Children's Hospital, Boston, during the period from 1937 to 1944. All of the patients were boys and ranged in age from 4 to 13 years. Three patients were injured in falls, 3 in shelling accidents, and 1 patient was struck by a falling object. One patient had been

treated for erythroblastosis fetalis five years before the splenic injury. The spleen of this patient weighed only 64 gm. and was microscopically normal except for the changes due to the trauma. There was no case of delayed rupture of the spleen.

A child who has sustained an injury causing rupture of the spleen usually complains of abdominal pain; frequently this pain is in the left upper abdominal quadrant and occasionally it is referred to the left shoulder. The pain is shortly followed by evidence of acute blood loss. On examination there are pallor, anxious facies, varying degrees of shock, and tenderness and maximum muscular rigidity in the left upper abdominal quadrant. If there is progressive and extensive bleeding there are signs of abdominal fluid.

One child had paroxysmal pain resembling that of intussusception. The pain was referred to the left shoulder in 3 of the 7 children. All 7 children had symptoms of acute blood loss but only 1 was in severe shock. In 5 there was abdominal tenderness and left upper quadrant muscle spasm. In no case was the "Ballance sign" present—increasing and nonshifting dullness in the left flank. In 5 patients the red blood count on admission had fallen below 3,500,000 and in 2, approximately to 2,500,000. The leucocyte count varied from 10,600 to 18,000. X-ray examination did not contribute to the positive diagnosis in any case.

Immediate surgery is indicated. Adequate whole blood and plasma is given, the plasma being used until compatible blood is obtained. The technique of splenectomy differs only from elective splenectomy in that the pedicle is sought immediately and controlled.

Postoperatively, daily platelet counts should be made after the third or fourth day in anticipation of a "platelet crisis." Heparin is given if there is any evidence of thrombosis or if the platelet count is over 800,000, and continued as long as the count remains over 800,000. EARL O. LATIMER, M.D.

Doan, C. A., and Wright, C.: Primary Congenital and Secondary Acquired Splenic Panhematopenia. *Blood, J. Hemat.*, 1946, 1: 10.

The spleen is an organ of multiple structures and many functions which normally are in a state of physiological balance. The processes of blood cell formation, blood cell sequestration, and blood cell destruction normally represent a delicately balanced splenic equilibrium, which may be upset because of congenital accentuation or diminution of a function, or because of secondary involvement of the spleen in some general constitutional disease. A large variety of disturbances in the circulating blood equilibria due to splenic dysfunction may occur. The definitive proof of the primacy of the splenic influence in any given instance is the favorable result of total extirpation of all splenic tissue, medical management having proved completely ineffective. Instability in splenic functional balance with respect to any one of the essential elements of

the blood passing through the spleen may be an inherited trait, as in congenital hemolytic icterus. Primary splenic panhematopenia is a syndrome in which, despite compensatory panmyeloid hyperplasia, the indiscriminate elimination of all circulating elements occurs. Such a state of splenic dysfunction may simulate panmyeloid hypoplasia.

Three cases are reported illustrating splenic panhematopenia, in all of which splenectomy was followed by immediate and lasting improvement in the abnormal blood picture and in the general condition of the patients. The first case was one of congenital splenic panhematopenia occurring in a 14 year old girl who had a chronic relapsing form of the disease. That splenic panhematopenia may occur as an acute fulminant medical crisis was illustrated by a case occurring in a 24 year old woman, who showed dramatic improvement following emergency splenectomy. The third case was an example of splenic panhematopenia secondary to Gaucher's disease in a 20 year old female. The latter patient's sister, at the age of 6, had been subjected to splenectomy for Gaucher's disease.

The authors' studies fully confirm Nargel's interpretation of splenic pathological physiology, but they would not limit it to Gaucher's disease. The advantage of observing and analyzing fresh, surgically removed splenic tissue in the supravitral technique, which identifies both the phagocytic cells and their engulfed contents, strongly incriminates the splenic macrophages in all of the so-called hypersplenic syndromes. Platelets, as well as leucocytes and erythrocytes, can be readily recognized when they are present within the living splenic phagocytes, and the proportion of each thus discovered, sequestered and being destroyed in the spleen, is generally a good reciprocal index of the cellular units available in the circulation when the bone marrow is not depressed.

The differential diagnoses which must be considered by the clinician in the syndrome are threefold: (1) hypoplastic bone marrow, either primary, idiopathic, or secondary to some noxious agent; (2) splenic panhematopenia secondary to some constitutional disease which involves the spleen predominantly and disturbs its finely adjusted physiological balance; and (3) primary splenic panhematopenia on a congenital or familial basis. Complete data from the adrenalin test and careful sternal marrow aspiration analyses should provide the information on which to base an opinion and advise therapy. Splenectomy in the first two mechanisms may result in a more or less temporary and abortive remission of the symptoms and signs related to the disturbed cellular balance, and it may or may not influence the fundamental underlying disease; but in the last named syndrome, in which the spleen apparently is primarily at fault, a prompt, complete, and permanent re-equilibration, both hematological and clinical, may be anticipated and predicted with some assurance.

JOHN L. LINQVIST, M.D.

MISCELLANEOUS

Moore, M. T.: Paroxysmal Abdominal Pain. *J. Am. M. Ass.*, 1945, 129: 1233.

In cases of abdominal pain without a demonstrable organic or psychogenic cause, a study should be directed to the possible existence of cerebral disease or dysfunction. Exact localization of cerebral representation of gastrointestinal activity and abdominal pain is still not fully determined, but most data point to cortical mediation and possibly diencephalic influence.

From the clinical approach, abdominal pain has been postulated as being a form of epileptic variant. Fits of varying forms, including abdominal pain, may result from a host of conditions producing either structural or physiological changes in the brain. Wechsler stated: "I would call attention to the occurrence of abdominal pain, at times simulating appendicitis, renal colic, gallbladder disease, and gastric or duodenal ulcers, in tumors of the brain. I have seen patients treated for a long time and even operated upon for abdominal syndromes which were the harbingers of brain tumors."

The author presents 6 cases which constitute a group of individuals in whom abdominal pain was the only symptom (or an outstanding one) present and unrecognized over a considerable length of time, and in whom thorough history taking, detailed neurological examination, and utilization of diagnostic aids, including electroencephalography, led to the consideration of the pain as a manifestation of focal symptomatic epilepsy.

The 6 cases presented have a common denominator: abdominal pain. In 2 cases this happened in practically a pure form, and in 1 case the predominant seizures consisted of abdominal pain occurring in wavelike attacks. These 3 cases had been studied quite intensively before the diagnosis of abdominal epilepsy was entertained; 2 of the patients showed

abnormal electroencephalographic findings. All 3 patients responded immediately and continuously to anticonvulsant therapy in the form of dilantin and bromides or phenobarbital.

Three of the 6 patients had a history of antecedent head injury. One presumably had cerebral angioneurotic edema following the injection of diphtheria antitoxin, with a sensitization or morbid change in the cerebral cortex, and 1 had tuberous sclerosis with undoubted morbid changes in the brain. No etiological background could be revealed in the sixth case. Thus, the majority of cases presented give evidence of disturbed cortical structure and function.

The 5 patients who were given anticonvulsants responded favorably and quickly to the use of dilantin alone or in combination with phenobarbital or bromides. Two patients in whom electroencephalograms were made before and during treatment with dilantin and phenobarbital demonstrated the damping out effect, by these anticonvulsants, of the abnormal cerebral discharges.

In 3 of the 6 cases, the patient gave a history of head injury. This, as a possible cause of abdominal epilepsy, is considered important at this time because of a strong likelihood of many cases of epilepsy or its variants finding their way into medical practice as the result of craniocerebral injuries and infections incident to World War II, and those which may appear with the return of the automobile and airplane to extended civilian use.

The criteria for diagnosis are based on (1) exclusion of intrinsic visceral disease, (2) adequate historical data, (3) attack pattern of an epileptic order, (4) associated epileptic show, (5) objective evidence of cerebral organic disease or dysfunction, and (6) the effect which anticonvulsant drugs produce on the symptom of abdominal pain and on the electroencephalogram.

DOUGLAS R. MORTON, M.D.

GYNECOLOGY

UTERUS

Scheffey, L. G.: Diagnosis and Management of Uterine Carcinoma and Sarcoma. *Surg. Clin. N. America*, 1945, 25: 1262.

A review of pelvic malignancies is presented. The author notes that carcinoma of the cervix is no respecter of the so-called cancer age, and that 27 per cent of cancer patients seen at the Jefferson Clinic, Philadelphia, were under 40 years of age. He advocates the use of biopsy on all suspicious lesions, and the necessity, in many cases, of splitting the cervix for a more careful inspection. The vaginal smear technique is used in his clinic, but it is admitted that a long period of training is necessary before one can be proficient in identifying abnormal cells which are characteristic of malignancy.

The author reviews the management of carcinoma of the cervix, and compares the results obtained from use of the radical Wertheim operation with those obtained from irradiation. He quotes statistics from many clinics which have used one or both methods, and concludes that irradiation is the treatment of choice in the great majority of cases. In the Jefferson Clinic the survival rate, based on a 5 year follow-up, was 47 per cent for early cases and 23.5 per cent as an over-all rate. The technique employed at the Clinic is discussed in detail and the use of deep roentgen rays through 4 external ports, combined with the transvaginal port, is favored. A massive dose treatment with radium follows the deep x-ray treatments.

The occurrence of carcinoma in the cervical stump following supravaginal hysterectomy is estimated at approximately 1 per cent, and the treatment of choice is irradiation. Carcinoma of the cervix in association with intrauterine pregnancy is noted as a combination of rare occurrence, with an estimated incidence of 1 case in 10,000 pregnancies. The use of biopsy is recommended, and precedence is given to management of the carcinoma over the possibility of obtaining a live baby.

The incidence of carcinoma of the fundus in patients under 40 is rare, and figures from the Jefferson Clinic place their average age at 59. The use of natural and synthetic estrogens in the management of symptoms of the menopause has frequently confused the diagnostic picture in postmenopausal bleeding, and stress is placed on the fact that diagnostic curettage is necessary when bleeding occurs. The author's management of fundal carcinoma is preliminary irradiation followed by total hysterectomy and extirpation of the adnexa in every patient who can tolerate surgical procedures.

It is estimated that sarcoma of the uterus occurs in approximately 3 per cent of all uterine malignancies. The treatment and prognosis is generally accepted to be unsatisfactory.

GEORGE BRADBURN, M.D.

Cirio, C. R.: Myometrectomy (Miometrectomia). *Obst. gin. lat. amer.*, B. Air, 1945, 3: 761.

In the treatment of myoma of the uterus the type of operation should be fitted to the conditions encountered in the individual, with avoidance of any tendency at systematization. The author, in fact, cites a number of operations which might be resorted to on occasion, and arranges them in order from the most conservative to the most radical. The list begins, of course, with polypectomy and curettage, continues with enucleation or myomectomy by the abdominal or vaginal routes; then comes the fundal amputation of Passeron and Beutner, and finally, he mentions his own operation, or myometrectomy. Four other types of operation, the partial amputations of the body of the uterus according to Aschner and Risolia; the hysteromyomectomy of Maunty Santos; the high, subtotal, and the low, subtotal hysterectomies, the latter combined with the implantation of endometrium in the stump, close his list of operations aimed at preserving the function of menstruation. Finally, the list contains, as most radical and sacrificing the menstrual function, the operations of low, subtotal hysterectomy without implantation of the endometrium, and total hysterectomy.

For myometrectomy the author not only claims the preservation of the menstrual bleeding itself, but further asserts that this operation will not hinder the synergism which exists between the endometrium and ovary. This is not solely due to the preservation of the endometrium but to the method of first loosening carefully from the uterus the broad ligament in its entirety before proceeding with the operation of amputating the upper part of the corpus uteri.

As for the technique of myometrectomy, it is briefly described in French in *La Presse Médicale* (1940, No. 90) and in Spanish in the *Journal of the International College of Surgeons* (1942, No. 6). Excellent photographs and diagrams render the general character of the operation obvious. Essentially, the operation is a vaginal amputation through the body of the uterus, followed by excision of the muscular wall of the uterus between the endometrium and perimetrium of the stump as far as the cervix; and perimetrium of the stump as far as the cervix; the inner tube of endometrium, with perhaps some attached muscular tissue, and the outer tube of perimetrium are left as intact as conditions permit. The two tubes are now intimately applied and sutured to each other and then the outer or so-called myometrial tube is closed across the top to leave the serosal tube is closed toward the vagina. Finally, the draining downward toward the vagina. Finally, the carefully preserved stumps of the broad ligaments are included in the remaining peritoneal flaps and the whole is sutured over the remaining uterine stump, the so-called peritonization.

Follow-up examinations usually show that the cavity of the child sized residual uterus is about 4 cm. in depth, and although pregnancy is excluded, as a rule the woman menstruates at her regular intervals and with almost normal abundance. In fact, 1 patient later developed a menorrhagia, which, however, proved to be the subsequent growth of a myoma of the cervix from an area so deep that it could not be reached by the operation itself. It is obvious, of course, that this operation should not be done on younger women (below 40 years of age) unless they have already satisfactorily fulfilled their rights and duties as a mother, nor on older women (above 48 years of age) who are already entering or have entered the menopause. Again, the bleeding in this operation, although not serious, is nevertheless a factor which requires a quick, deft procedure, and the method should not be attempted by other than an adept.

The author's material now includes 141 operations with a follow-up on 91; in 12 (13%) menstruation has not returned, while in 79 (87%) it has reappeared; however, in a new group of 48 patients operated upon there has not been a single instance of amenorrhea. These last excellent results are attributed by the author to the perfecting of his technique, especially the separating of the inner or myometrial tube by means of the bistoury, and rejecting the electric knife for this part of the operation, as well as the careful preservation of the broad ligament with regard to its blood supply and innervation, which permits a more perfect functioning of the synergistic relationship existing between the ovary and the endometrium.

The author's statistics, which are the most important recorded up to the present time, give a mortality for myometrectomy of only 1.41 per cent.

JOHN W. BRENNAN, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Magnusson, W.: Roentgen Diagnosis of Tuberculous Salpingitis (Ueber das Röntgenbild bei tuberkulöser Salpingitis). *Acta radiol.*, Stockh., 1945, 26: 265.

As a rule uterosalpingography is not considered to be a diagnostic method by which inflammatory lesions of the fallopian tubes such as gonorrheal, tuberculous, and nonspecific salpingitis can be distinguished from each other. The only exceptions are salpingitis isthmica nodosa and endometriosis of the tubes.

The author studied the roentgen findings in 12 histologically proved cases of tuberculous salpingitis and compared them with films obtained in 200 cases of tubal occlusion caused by tuberculosis and various other conditions. The nonpatency of the tubes was demonstrated in all cases of both groups by 24 to 48 hour follow up films taken in the erect position for visualization of the fluid levels. These films showed retention of the contrast material (perabrodil or iodized oil) in the tubes.

In 9 cases of the first group irregularly serrated, ragged contours of the visualized tubes were found to be associated with from pin head to rice kernel sized intraluminal filling defects. Three cases displayed destruction of the tubal wall with abscess and fistulalike dilatations of the tubes. The 24 hour films showed retention of the contrast material in irregularly shaped saccular pools in 6 cases, most of them containing fluid levels.

The author concludes that the roentgen diagnosis of tuberculous salpingitis is possible in many cases since the described findings are rare in other forms of salpingitis.

GERIART S. SCHWARZ, M.D.

Spangler, C. M.: Operations for Sterility. *Surg. Clin. N. America*, 1945, 25: 1345.

The author states that the surgical approach to the problem of sterility in the woman of childbearing age may be successfully followed in some instances. If possible, the cause of the sterility is ascertained, following which a test for tubal patency is made. Surgery is never attempted in the presence of acute or subacute pelvic infection.

The choice of operative procedure depends upon the location of the obstruction. In extensive tubal obstruction, the Estes or the Tuffier operation must be performed. The former consists in the excision of the uterine cornu and the attachment of the denuded surface of the ovary to the exposed ostium, care being taken to preserve the blood and nerve supply. The Tuffier operation consists in making an opening in the posterolateral wall of the uterine cavity, into which the ovary is projected. The incidence of pregnancy following these operations is about 8 and 4 per cent respectively.

The Bonney operation is used in cases in which the obstruction lies in the outer third of the tube. It consists of an amputation proximal to the site of the occlusion, testing the tube for patency, placing a No. 9 catheter in the outer third of the tube, and a Bonney clamp over the tube and catheter 1.5 to 2.5 cm. from the amputated end. A circular incision is made at the end of the clamp through the muscularis, and the mucosa is everted, bringing it onto the serous coat. The ovary is then suspended to the lateral pelvic wall.

Obstruction in the proximal or medial portion of the tube offers the greatest opportunity for success. A modified Holden technique is used where the oviduct is divided distal to the site of obstruction, and the closed portion is then freed from its broad ligament attachment. The uterine cornu is excised and the patent end of the tube is inserted.

Postoperative treatment consists of a Rubin insufflation in from 10 to 14 days. At the end of 6 weeks, 92 per cent of the patients in this series exhibited patent tubes. CATHERINE B. HESS, M.D.

Knight, R. van Dyck: Tubal Sterilization. *Am. J. Obst.*, 1946, 51: 201.

Two hundred and thirty-three tubal sterilizations performed during a 10 year period are reviewed by

the author in an effort to determine which type of operation offers the highest incidence of success. The Pomeroy sterilization is a safe, simple, sure, and rapid procedure. The reported failures of this operation are 50 per cent fewer than those for the Madlener sterilization.

The Pomeroy sterilization avoids mechanical and biological hazards which are inherent to other types of tubal sterilization. EDWARD L. CORNELL, M.D.

Dionisi, H., and Ferraris, L. V.: Ovarian Struma with Hyperthyroidism (Struma ovarica con hipertiroidismo). *Obst. gin. lat. amer.*, B. Air, 1945, 3: 797.

A woman of 46 years, who had had 4 normal pregnancies and deliveries, had been undergoing rather satisfactory treatment for diabetes for 5 years when she began to lose weight and strength, and developed tremor, exophthalmos, and an enlarged thyroid gland. Her basal metabolism varied between +37 and +54 but after subtotal thyroidectomy it dropped to +12, the symptoms of hyperthyroidism disappeared, and the patient gained 10 kgm.

Two years later the patient again sought medical advice, having been suffering again from nervousness for about 6 months. At this examination there was observed a distinct exophthalmos, tremor, and some muscular hypotonia. No enlargement of the residual thyroid tissue in the neck could be determined, nor could any aberrant thyroid glands be found. However at vaginal examination a spherical tumor, the size of an orange, could be felt to the right of the uterus. The diabetes could be controlled adequately with insulin, but the other symptoms continued in spite of iodination, the basal metabolism measuring +52 10 days later.

The ovary seemed to be involved in the tumor mass and the whole was removed under local anesthesia with .50 per cent novocain. A month later the metabolism was down to +8. A year later the patient was in perfect health and had gained 12 kgm.

Histological examination exhibited the usual lack of uniformity for tumors of this sort, that is, there were areas which very much resembled a colloid goiter, others simulating the typical Basedow picture, and, finally, still other areas suggesting the fetal type of parenchymatous hyperplasia. Scattered about were remnants of the original ovary.

Although the authors were not in a position to conduct special chemical or biological investigations, they believe that in view of the clinical picture and the morphologic aspect of the tissues there can be no doubt that the thyrotoxic picture was occasioned by the ovarian struma. JOHN W. BRENNAN, M.D.

EXTERNAL GENITALIA

Rodrigues, F. V.: Some Lesions of the Vulva (Sobre algumas lesões vulvares). *An. brasil. gin.*, 1945, 20: 271.

A statistical review of the cases seen in the Gynecological Clinic of the National School of Medicine

at Rio de Janeiro over the 10 year period from 1935 to 1945 is given. Ninety-three lesions were encountered among 3,180 hospitalized cases, and 221 lesions among 6,050 out patients. Some patients were included in both groups, but in order of frequency disease of the Bartholin glands was the most common, followed by luetic manifestations, and other types of ulcers, dystrophies, and neoplasms. Neoplasms were seen in .9 per cent of the out patients and 6.45 per cent of the in patients. Mycotic infections were seen in 2.21 per cent of the out patients.

A tabular list of the various lesions in both groups is given in the original article and is accompanied by illustrative photographs. One case of cylindroma is presented. HIRSH T. LANGSTON, M.D.

MISCELLANEOUS

Lang, W. R.: Blood, Blood Derivatives, and Blood Substitutes in Obstetric and Gynecologic Practice. *Surg. Clin. N. America*, 1945, 25: 1485

Lang, in a survey of blood, its derivatives and its substitutes, stresses the use of such products in the practice of obstetrics and gynecology where so many acute emergencies necessitate immediate and efficient restoration of blood volume and oxygen carrying capacity to the patient. The various parenteral routes of administration are discussed, and the author favors the intravenous and intramedullary routes.

Often, not enough whole blood is used, and it is believed that the response on the part of the patient, rather than the volume of blood administered, is the best indicator. The use of plasma and other substitutes is but a temporary measure in the treatment of acute blood loss.

The author summarizes the importance of the Rh factor in hemolytic transfusion reactions, in certain complications of pregnancy, and in neonatal anemias. He believes that in the administration of red cell suspensions to replace lost cells, those of Rh negative donors (even though the plasma of such donors contain anti-Rh antibodies) may safely be given to erythroblastotic infants, or to the mothers of such children.

The various colloidal plasma substitutes are listed and discussed. The author apparently favors the use of albumin and ascitic fluid.

GEORGE BRADBURN, M.D.

Greene, R.: D.B.E.: A New Synthetic Estrogen. *Brit. M. J.*, 1946, 1: 9.

D.B.E. (α -di-(p -ethoxyphenyl)- β -phenyl bromo-ethylene) is a new synthetic estrogen which is absorbed from the alimentary tract, but differs from other orally active estrogens in having a prolonged action, whether it is given by mouth or injection.

In 6 patients suffering from the vasomotor symptoms of the climacteric, satisfactory relief was obtained with an initial dose of 1 or 2 gm., followed by a maintenance dose of from 100 to 300 mgm. once weekly. Less satisfactory results were obtained in 3

cases of uterine atrophy. D.B.E. was ineffective in controlling carcinoma of the prostate in 3 cases.
HENRY C. FALK, M.D.

Way, S.: D.B.E. in the Treatment of Menopausal Symptoms. *Brit. M. J.*, 1946, 1: 10.

D.B.E. (α -di-(p -ethoxyphenyl)- β -phenyl bromo-ethylene) is a synthetic estrogen with a prolonged action. This substance was used to relieve menopausal symptoms in 11 patients who had undergone surgical or radiological castration: 5 were completely relieved, 3 were greatly relieved, and 3 showed no response. The dosage required for the relief of these symptoms is an initial dose of 2 gm., followed by a maintenance dose of 0.2 gm. weekly. Mild cases may require only half this dosage. The side effects of other synthetic estrogens have been noticed with D.B.E.

It appears from this small series that D.B.E. is probably not as effective as stilbestrol in the relief of menopausal symptoms. It is probable that its sole advantage is that it needs to be administered infrequently and not daily, as with other synthetic estrogens.
HENRY C. FALK, M.D.

Rubin, I. G.: Therapeutic Aspects of Uterotubal Insufflation in Sterility. *Am. J. Obst.*, 1945, 50: 621.

The extent to which some degree of patency can be produced by tubal insufflation alone or by any additional measures, such as diathermy treatment or the more potent hormonal extracts, will determine the conceptional possibilities in women whose sterility is traceable chiefly to tubal pathology. It was with this object in mind that the author made the following statistical analysis in 590 personal cases of pregnancy preceded by uterotubal insufflation.

Primary versus secondary sterility. In the author's personal series there were 2,014 patients with primary sterility. Of these, 358 (17.77%) became pregnant. There were 1,186 patients with secondary sterility, of whom 232 (19.56%) became pregnant.

One hundred and forty-six of the patients who became pregnant were between the ages of 20 and 25 years, and 250 were between the ages of 25 and 30 years. One hundred and eighty-four patients (31.19%) were 30 years of age or over when they sought relief; of these, 34 were between the ages of 35 and 40 years, and 6 were over 40 years old.

In 7 of the successful cases with high grade strictures, lipiodol also was employed. In 3 cases, insufflation had been done once before lipiodol was employed; in 3 cases insufflation had been done 3 times, and in one case, 4 times. In 4 of these cases insufflation also followed the lipiodol injection—once in 2 cases, 4 times in 1 case, and 7 times in the fourth case before pregnancy ensued. The therapeutic efficacy of lipiodol in these 7 cases is difficult to appraise because 29 insufflations altogether had been done before or after the 7 single lipiodol injections.

TABLE I.—TUBAL STATUS IN 590 PATIENTS WHO BECAME PREGNANT

	Number of Cases	Number of Pregnant Cases	Percentage
Normal patency	1,210	316	26.12
Adherent tubes	538	135	25.09
Strictured tubes	379	118	31.13
Spasm and normal patency	134	21	15.74
Total	2,261	590	98.08

TABLE II.—THE EVENTUALITY OF PREGNANCY IN 517 CASES

	Number of Cases	Percentage
Term babies only—born alive	383	74.08
Premature babies—born alive	4	.77
Premature and term babies—born alive	4	.77
Premature and incomplete abortions	2	.39
Stillbirth at term	2	.39
Stillbirth	2	.39
Spontaneous abortions	81	15.67
Spontaneous abortions and term babies	26	5.03
Tubal pregnancy—born alive	9	1.74
Tubal and term pregnancies—born alive	4	.77
Total	517	100.00

Of the 590 patients who became pregnant, 11 were treated with small doses of radium for delayed and scanty periods, and 1 patient received a larger dose for menometrorrhagia. Eight of the 12 patients became gravid within 1 year of the use of radium, and 4 within the first 6 months. Similarly, 29 patients had received x-ray and insufflation therapy before becoming gravid.

Three hundred and seventy-eight, or 64.07 per cent, of the pregnancies occurred within the first 6 months of the test; 108 pregnancies occurred within the second 6 months.

Ninety-four patients who became pregnant following insufflation subsequently encountered renewed difficulty in conceiving. Another insufflation was again succeeded by pregnancy.

EDWARD L. CORNELL, M.D.

Siegler, S. L.: The Value of Physiological Substrates in Sperm Migration in Selected Cases of Human Infertility. *Am. J. Obst.*, 1946, 51: 13.

It does not appear improbable that the use of a Ringer glucose precordial irrigation, at the most favorable period, makes several real contributions toward increasing the possibilities for sperm migration by furnishing additional sugar and isotonic electrolytes for stimulation of the cellular metabolism and motility, through promotion of a propitious pH of the mixture of vaginal secretions, by altering the viscosity of both the distal cervical mucus and the male ejaculate in the presence of a favorable isotonic substrate, and by providing a less abrupt metabolic shock for the spermatozoa.

When one considers the manifold aspects which can alter the surface substrates and glucose levels of

the semen in the vaginal secretions, it becomes more obvious that Ringer glucose isotonic solution used as a precoital irrigation merits a definite place in the armamentarium of the physician confronted with infertility problems.

The application of these important animal husbandry and preclinical laboratory observations for the relief of human infertility, in carefully selected cases, is discussed. In 106 couples giving a history of from 1 to 14 barren years, Ringer glucose isotonic solution was used precoitally as a vaginal irrigation, and the author is able to report 29 successful conceptions, a salvage of 28.3 per cent from this group of infertile patients.

EDWARD L. CORNELL, M.D.

Sampson, J. A.: The Pathogenesis of Postsalpingectomy Endometriosis in Laparotomy Scars. *Am. J. Obst.*, 1945, 50: 597.

Seventeen cases of laparotomy scar endometriosis were studied. The first operation, in all but 1 case, consisted of bilateral salpingectomy or tubal sterilization followed by intentional or accidental ventrofixation of the uterus. In the 1 case in which salpingectomy had not been done, the scar endometriosis followed a myomectomy. In all but 1 of the 16 postsalpingectomy cases, the scar, together with the uterus, was removed at the second operation. In this 1 case the endometriosis, apparently fused with both uterine cornua, was so extensive that only a portion of it and the remaining ovary were removed. In all but 2 of these 15 specimens the scar endometriosis was fused with a uterine cornu. In 1 of these 2 cases the fundus was not in actual contact with the wound at the close of the first operation but the left cornu became connected with the scar by the remains of a long drainage tract. In the other case the scar endometriosis was fused with the center of the fundus and not with either uterine cornu, although stump endometriosis was present in both cornua. In this case the scar endometriosis was derived from the mucosa of the fundus by continuous invasion in the attempted repair of an evident rent

in the uterine wall, probably caused by a ventrofixation suture which had penetrated the uterine cavity.

Endometriosis was found about the tubal stumps in the 13 uterine cornua which were adherent to the scar endometriosis, as well as in the cornu not in actual contact with the scar but connected with it by a long drainage tract. It was present about the tubal stumps in both cornua in 11 of these 14 uteri, but in only 1 instance had the endometriosis in both cornua invaded the scar and produced 2 foci of endometriosis in it. In the remaining 10 cases, the scar endometriosis was derived from only one tubal stump, and that about the other stump was confined to the cornu itself.

The scar endometriosis was derived from the mucosa of a tubal stump by continuous invasion in 10 specimens. It probably arose in a similar manner in 3 others. In 2 additional specimens such an origin could not be excluded although in 1 the endometriosis might have been of transplantation origin and in the other, secondary to a possible peritoneal endometriosis of the uterine cornu. Transplantation endometriosis was possibly present in 3 scars.

An interesting feature of postsalpingectomy endometriosis is that the ectopic mucosa, which can be shown to have had its origin in the mucosa of a tubal stump and to have grown from it by continuous invasion, may not only retain the structure of the tubal mucosa, thus being actually an endosalpingosis, but may also assume both the structure and function of the uterine mucosa, including its reaction to menstruation and pregnancy, and thus produce true endometriosis.

Mucosa of the uterine type was present in all of the specimens of postsalpingectomy scar endometriosis. In some specimens the endometriosis of the uterine cornu, which was proved to have been derived from the mucosa of the intramural part of the tube, was definitely of the tubal type. However, after these tubules had penetrated the scar, typical uterine mucosa appeared in and about them.

EDWARD L. CORNELL, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Scott, W. A.: Selective Treatment of Antepartum Hemorrhage. *Am. J. Obst.*, 1946, 51: 48.

Selective treatment of 191 cases of placenta previa resulted in a mortality of 2.6 per cent, and of 139 cases of accidental hemorrhage in a mortality of 2.9 per cent.

These results are comparable to those obtained by routine section in the treatment of these conditions and may avoid the additional risk of subsequent pregnancies in patients who have undergone cesarean section.

All cases of antepartum hemorrhage should be treated in the hospital, if at all possible, but as the diagnosis cannot always be accurately made when the first bleeding is only slight, this will entail the hospitalization of patients who may subsequently be proved to have neither placenta previa nor accidental hemorrhage.

In most emergencies of medical practice, when special skill is not available, conservative measures of treatment are usually in the best interests of the patient, but if skilled judgment is not available in placenta previa and probably in accidental hemorrhage, a radical method of treatment, namely cesarean section, is probably advisable.

EDWARD L. CORNELL, M.D.

LABOR AND ITS COMPLICATIONS

Hingson, R. A.: The Control of Pain and Fear in the Management of Labor and Delivery. *Surg. Clin. N. America*, 1945, 25: 1352.

The author presents an evaluation of the most commonly used analgesics in labor with particular emphasis on the necessity for controlling pain and fear. Since Pearl Harbor Day, 1941, approximately 12,000,000 babies have been born in the United States, with an estimated annual loss of 624,000 babies at birth or during the first year of life. This far exceeds our losses due to war.

The physician should devote more attention to the protection of the obstetrical patient from pharmacologic intoxication or overdosage of the analgesic drugs while attempting to provide control of the pain, and should use more psychology in the management of labor and delivery. No one single agent or method is suitable for every case.

Pain relief in obstetrics can be attained only in hospitals where there is teamwork among the obstetrician, anesthetist, and nurse. At the present time in the United States there are seven methods commonly used. The most popular, used in 60 per cent of deliveries, is the use of the barbiturates. The second is the use of chloroform and open drop ether. The third is the use of nitrous oxide oxygen analgesia with labor pains; the fourth, the use of rectal anal-

gesia with either paraldehyde or ether, or both. Within the past three years caudal analgesia has moved up to fifth place. The author personally supervised 5,000 labors and deliveries under caudal analgesia. The recent introduction of demerol as an agent has provided the means of combining it with scopolamine or the barbiturates and this agent ranks sixth place. In seventh place are local perineal infiltration, and spinal, paravertebral and peridural block.

Several methods for amnesia were reported upon by various obstetricians; the use of scopolamine was discussed by Royster. This consists of giving from 3 to 4½ gr. of nembutal, plus 1 c.c. (1/130 gr.) of hyoscine hydrobromide. Forty-five minutes after the initial dose another cubic centimeter of hyoscine is given, and in another 45 minutes 0.5 c.c., and this is repeated every 1½ to 2 hours.

Scopolamine is also administered very successfully in combination with morphine, demerol, and the barbiturates.

Rudolph submitted a method for rectal analgesia. A soda bicarbonate enema is given first. When the pains are hard and regular, from 4½ to 6 gr. of nembutal are given, and when the patient becomes restless again ether (ether 2½ ounces, paraldehyde, 2 drachms, olive oil, q.s. 4 ounces) is given rectally. The safety of rectal ether analgesia in obstetrics is one of its greatest advantages.

It is also noted that paraldehyde can be given by mouth, the dose being about 20 c.c. Port wine is used as a vehicle. Paraldehyde plus 1.5 c.c. of benzyl alcohol can be instilled into the rectum.

Caudal analgesia is discussed as a technique to produce total analgesia without amnesia or anesthesia. The agent recommended is 1.5 per cent metycaine in isotonic solution of the three chlorides. A trial dose of 8 c.c. is given to eliminate the danger of intraspinal injection. Satisfactory relief was obtained in 92 per cent of 3,000 cases at the Philadelphia Lying In Hospital. Three maternal deaths occurred: the first was due to intraventricular hemorrhage, the second to unexplained hyperpyrexia (in a toxemic multipara with inadequately treated syphilis), and the third to exacerbation of an endocarditis.

Siever reported that continuous drip caudal analgesia was advantageous because: (1) the chance of infection was decreased, (2) the level of anesthesia was constant, (3) there was more uniform pressure within the caudal canal, and (4) the total amount of anesthetic required was decreased.

Continuous spinal anesthesia was also mentioned for use in selected cases. From 25 to 50 mgm. of 2 per cent procaine or from 15 to 30 mgm. of 1.5 per cent metycaine are used. This is the one method which, when properly administered, absolutely protects the baby from transplacental intoxication.

In controlling fear in labor a quiet, soundproof room with cheerful furnishings is essential. Caudal analgesia allows the patient to relax, read, and to enjoy her surroundings. This technique has returned to womanhood the experience of hearing her baby's first cry, which she previously had to sacrifice. Thus in modern obstetrics the babies can and must be spared placental narcotization.

CATHERINE B. HESS, M.D.

Ricel, J. V., and Marr, J. P.: The Physick-Sellheim Principle of Extraperitoneal Cesarean Section. Elucidation of a Technique Based on 175 Cases. *Am. J. Surg.*, 1945, 71: 3.

The author's technique of extraperitoneal cesarean section is described in detail. This operation was performed in 175 cases, including "clean" as well as potentially or actually infected women, with 1 maternal death and 7 fetal deaths. The bladder was injured on 6 occasions; in all instances repair was followed by an uneventful recovery.

After examination and dislodgment of the impacted fetal head, the bladder is catheterized and the catheter removed. A completely empty bladder facilitates the operation and reduces bladder injury to a minimum. With the patient in moderate Trendelenburg position, a symmetrical $5\frac{1}{2}$ inch Pfannenstiel incision is made, the aponeurosis of the recti and oblique muscles incised, the median raphe of the recti muscles cut, and the recti muscles are separated from the underlying transversalis fascia.

The bladder lies beneath the transversalis fascia and is completely enveloped (anteriorly and pos-

teriorly) by the vesical fascia. Finger massage of the bladder and its fascial coats helps to contract the bladder and loosen this viscus from its fascial capsule (Fig. 1).

The fascia transversalis and anterior vesical fascia are grasped with two curved Kelly clamps 1 inch below the bladder dome in the midline, and incised between these two clamps (Figs. 2 and 3). All laminations of the fasciae are cut down to a layer closest to the musculature of the bladder. This opening is enlarged laterally to permit the intrusion of the index finger or Kelly clamp, and the liberated fasciae are incised arclike, in a curve down to Poupart's ligament, to expose the right paravesical fossa. The urachus, if fibrous, must be cut with care.

The right paravesical fossa is further exposed by careful and vigorous retraction to exhibit the lateral wall of the bladder, the outermost portion of the peritoneal reflection, and the fascia uteri. The bladder is displaced laterally and downward toward the symphysis. The transparent fascia uteri is incised just below the peritoneal fold to permit insertion of the index and middle fingers (Figs. 4 and 5). By finger dissection from right to left, the bladder is separated and elevated to reveal the edge of the peritoneal fold, the dome of the bladder, the fascia uteri, and the posterior vesical fascia (the two fasciae as one structure). The fasciae are incised with scissors between the dome of the bladder and the peritoneal fold from the right to the left side of the bladder to uncover the lower uterine segment.

A 3 inch crescentic incision is made into the lower uterine segment and stay sutures are inserted to

Fig. 1. Finger massage of flattened, empty bladder. This procedure helps to contract the anesthetically relaxed bladder musculature and to loosen viscus from fascial capsule.

Fig. 2. Grasping and incising of the fascia transversalis and fascia vesicae anterior 1 inch below bladder dome, exactly in midline. Both fasciae are laminated. Terminal lamination on the bladder musculature is left to facilitate decapsulation and protect vesical vessels.

Fig. 3. Peritoneal and fascial relationships to the bladder and lower segment exactly in the midline. Cross (x) indicates the point of incision of the fascia transversalis and fascia vesicae anterior as portrayed in Figure 2.

Fig. 4. The paravesical fossa (right) is exposed to present the lateral wall of bladder, the end of the posterior peritoneal fold, and the fascia uteri. The posterior peritoneal fold lies between the posterior vesical fascia above, and the fascia uteri below.

Fig. 5. The relationship of the fasciae to the displaced bladder and posterior peritoneal fold in the midline. Cross (X) indicates the area where the fascia uteri is incised to liberate the lower segment from the fascial covering and permit upward retraction of the peritoneal fold.

Fig. 5.

Fig. 6.

Fig. 7.

Fig. 6. Vertex in the anteroposterior position with the solid obstetrical blade in place over the brow. Delivery is facilitated by fundal pressure exerted against the obstetrical blade.

Fig. 7. The relationship between the cut fascia, bladder, and cut surfaces of the lower segment. Diagrammatic representation of Figure 6. (Courtesy of American Journal of Surgery.)

serve as guides and for hemostasis (Figs. 6 and 7). All retractors are now removed and the fetus is delivered by a solid obstetrical blade or version. The delivery of the placenta is preceded by the use of pituitrin and ergotrate. The uterus is packed with iodoform gauze and the incision closed with two

layers of No. 0 chromic sutures. The bladder is elevated to its original position. The transversalis fascia is coated with interrupted sutures. Sulfanilamide powder is sprinkled in the operative field and a rubber tissue drain is inserted.

GEORGE BLINICK, M.D.

Ullery, J. C.: Continuous Spinal and Continuous Caudal Analgesia in Cesarean Section. *Surg. Clin. N. America*, 1945, 25: 1382.

The marked narcosis of babies delivered under inhalation anesthesia and heavy drug sedation has been one of the highest causes of infant mortality. This report shows the indications, technique, and advantages of continuous caudal and spinal anesthesia for cesarean section as a means of eliminating this narcosis.

The advantages of continuous spinal anesthesia are as follows:

1. A smaller initial dose is used. Thus any untoward toxic symptoms will be minimal, and most of the drug can be rapidly withdrawn.
2. The anesthesia is easily controlled.
3. The ease of administration and speed is advantageous.
4. There is a definite decrease in postoperative complications.
5. An excellent contraction of uterine musculature occurs.
6. There is an absence of narcosis in the infant.
7. Excellent abdominal relaxation is present.

The technique consists in giving 1½ gr. of barbiturate an hour before operation. The needle is inserted between the first and second, or second and third lumbar interspaces. Eight cubic centimeters of fluid are withdrawn and mixed with the anesthetic agent and reinjected. This agent is usually from 25 to 40 mgm. of procaine. The level is maintained by the further injection of from 0.5 to 1 c.c. of procaine. The blood pressure, pulse, and respirations are taken every 5 minutes. If the systolic level falls to 90 mm. or less, ¼ gr. of ephedrine hydrochloride is given intramuscularly, or glucose solution or plasma is given intravenously. After the baby is extracted ¼ gr. of morphine is given hypodermically. Following the delivery of the placenta, ergotrate is given intramuscularly. At the completion of the operation, the remaining drug is partially removed by the aspiration of from 1 to 2 c.c. of spinal fluid.

A contraindication to this type of analgesia is the patient who is in poor condition because of severe hemorrhage.

The advantages of continuous caudal anesthesia are practically the same as those of spinal anesthesia. It is also particularly valuable in patients with cardiac or respiratory disease, and in patients who may have had an initial test of labor under caudal anesthesia and in whom the need for section arises. In severe toxemias in which cesarean section is required, the symptoms and blood pressure elevation are alleviated during and following operation.

The contraindications are listed as follows: (1) gross deformities of the spine, (2) tumors which narrow the spinal canal, (3) local infection around the sacral hiatus, (4) a history of sensitivity to the anesthetic agent, (5) profound anemia or shock, (6) placenta previa, and (7) hysterical patients.

The safety, controllability, speed, and ease of administration of spinal analgesia make this an

outstanding analgesia in the obstetrical armamentarium. Continuous caudal analgesia offers the same safety to the child and mother although it requires a specially trained anesthesiologist for its administration and supervision. CATHERINE B. HESS, M.D.

NEWBORN

Rothe-Meyer, A., and Hickmans, E. M.: Decrease of the Serum Cholesterol Ester in Hemolytic Disease of the Newborn. *Arch. Dis. Childh.*, Lond., 1945, 20: 160.

It has long been recognized that jaundice occurring in hemolytic disease of the newborn cannot be explained as a pure hemolytic icterus. The severity of the jaundice, the positive Van den Bergh reaction, and the pathological changes in the liver all point to a toxic injury of the liver. Furthermore, some cases are associated with "kernikterus" or with the late development of cirrhosis.

It is well known that the serum cholesterol and its partition may exhibit characteristic changes in diseases of the liver. Obstructive jaundice is characterized by a hypercholesterolemia, affecting both the free and the ester fraction, which parallels the degree of hyperbilirubinemia. On the other hand, in acute parenchymatous degeneration, especially toxic and infectious hepatitis, the values for total cholesterol are normal, or slightly subnormal, and show no relationship to the bilirubin values. The outstanding change is the lowering of the ester fraction, which mirrors the severity of the liver damage. In the severest cases the ester fraction is low or absent, and remains so until the fatal end; in less severe cases the low values rise to normal with clinical improvement; and in mild cases there is only moderate depression of the ester values.

As a part of the investigations on liver function in infancy, determinations were made of the serum cholesterol and its partition in a group of infants suffering from hemolytic disease of the newborn. This article records the results and attempts to assess their significance. The subjects for investigation were 14 patients at the Children's Hospital, Birmingham, Alabama.

The changes in the cholesterol partition in 9 of the 14 cases of hemolytic disease of the newborn were quite similar to those demonstrated as characteristic of acute toxic injury of the liver. No explanation could be offered for the fact that in 5 cases in the series no such changes were found.

ERNEST E. ARNHEIM, M.D.

MISCELLANEOUS

Power, H. A., and Cravotta, C. A.: Penicillin in Obstetrics. *Pennsylvania M. J.*, 1946, 49: 491.

This is a concluding report by the authors on penicillin used in 112 obstetric patients. The original report outlined the indications, contraindications, and limitations of sulfonamide therapy, and compared these factors with those involved in penicillin

therapy. The dosage used in the cases treated varied from 100,000 to 1,610,000 units.

The following is a list of the conditions which were treated with penicillin and the results obtained:

Acute mastitis—25 cases. Erythema and cellulitis diminished 50 per cent within 24 hours, and usually disappeared in 48 hours.

Cesarean section—26 cases. Thirteen were treated prophylactically and 13 for active infection. In the latter group the hospital stay was from 14 to 42 days.

Endometritis—20 cases. The prophylactic administration of penicillin following prolonged rupture of the membranes, for inertial labors, and to infected patients assured a smoother convalescence and shorter hospital stay.

Septic abortion—23 cases. Penicillin was found to be particularly effective in patients with a low hemoglobin as it had no influence on the red blood cells and hemoglobin levels.

Gonorrheal infection—5 cases. All of them were cured.

Postpartum cellulitis. No conclusions could be drawn from the results in these cases.

Omphalitis. This condition in the newborn responded quickly to penicillin.

The conclusions drawn in the first report of these investigators were confirmed by this larger additional series of cases. The absence of mortality and the decrease in length of hospital stay were most gratifying.

CATHERINE B. HESS, M.D.

Laqueur, W. A.: A Morphological Study on Chorionic Epithelial Proliferations Based on 10 Cases. *J. Obst. Gyn. Brit. Empire*, 1945, 52: 403.

The relationships between the development of the trophoblast and (1) the normal or penetrating placenta, (2) the simple hydatidiform mole, and (3) the chorioepithelioma are elucidated from histopathological studies of 10 cases. The modern concept of the trophoblast is that it produces the many cell types of the chorionic epithelium in successive stages of differentiation. The earliest stage consists of the Langhans cells which infiltrate like malignant tissue and the secondary formation consists of the syncytial cells which appear whenever the Langhans cells come in contact with liquid material. The function of these cells is to nourish the fetus by further proteolytic liquefaction of the maternal tissue. Syncytial cells also appear when local conditions become less suitable for cell nutrition, hence their appearance occasionally in nonliquefied tissues. The so-called pathological "syncytial giant cells" develop from the trophoblast but appear far from the placental site and can maintain themselves in the maternal tissues for a long period. Degeneration of chorionic epithelium produces the so-called fibrinoid coagulation which (1) forms a demarcation zone along the "stripe of Nitabuch" (a maternal barrier against the invading trophoblast), and (2) appears at sites of irregular proliferation of the chorionic epithelium either in the marginal vessels or in the myometrium.

The ovum imbeds itself when the trophoblast has developed the power to dissolve maternal tissues. Gradually the defense of the maternal tissues grows stronger, as the invasive power of the chorionic epithelium weakens, eventuating in the so-called "histiotrophic" phase of the trophoblastic development when the trophoblast nourishes itself at the cost exclusively of the maternal tissues. The trophoblast, its task fulfilled, disappears soon after the tenth week of pregnancy, leaving behind only the epithelium of the villi. The fetal stroma does not exist during the histiotrophic phase, but appears later when the villi first appear and is not vascularized; its development comprises the so-called cytotropic phase of growth which is found in the chorioepithelioma.

The pathological problem is to evaluate abnormal chorioepithelial proliferation, which upsets the balance between the destructive power of the cells of the young trophoblast and the maternal defense mechanism which comes into full action only slowly and progressively.

Four cases are presented which illustrate non-malignant chorionic invasion and the intimate reciprocal interference of maternal and fetal parts: 2 of abortion, 1 of myoma uteri, and 1 of spontaneous rupture of the uterus and persistence of the trophoblast. The presence of chorionic giant cells, noted in the pathological specimens of the 4 cases, is not necessarily indicative of malignancy unless the cells persist beyond the fourth week after abortion or delivery, and then only if they appear in large numbers. The presence of placental remains in the specimen also argues against malignancy. A fully developed decidua acts as a barrier against the abnormal proliferation of chorionic elements and especially of the giant cells. In pregnancy in an abnormal uterus, in endometriosis, or in the presence of a hydatidiform mole or placenta previa, these giant cells are seen in large numbers. In such cases, determinations of the gonadotropic hormones in the urine should be carried out, as well as close clinical check-ups, either to substantiate or rule out the presence of malignancy.

Three cases illustrating the increased proliferative power of the chorionic epithelium are presented, a case of spontaneous rupture of the uterus, and 2 cases of hydatidiform mole. In the first case enormous destruction was found in the presence of morphologically unaltered chorionic epithelium, and the muscle showed extensive necrosis, fibrinoid degeneration, and chorionic elements, singly and in masses, eroding and obstructing the vessels. The second case demonstrated a hydatidiform mole *in situ* penetrating deeply into the muscle, the penetrating cells consisting mainly of small Langhans cells and showing few degenerative changes; they massively infiltrated all of the layers, undermined the margins of the neighboring tissues, and infiltrated the venous sinuses. The third case demonstrated a hydatidiform mole showing excessive proliferation of the epithelium, with a preponderance of syncytial

cells and associated with typical puerperal changes; there was also a metastasis to the vulva. It is concluded that a diagnosis of malignancy (at best a difficult one to make on purely morphological grounds) should be based on (1) a preponderance of epithelial over stromal cells in the invading trophoblast, and (2) independent epithelial proliferation in at least one place (cytotrophic growth). The close association of epithelial elements, both syncytial and Langhans, with villous stroma argues against malignancy.

Three cases are described which showed chorionic proliferation without villous stroma, 2 of chorioepithelioma and a third of nonmalignancy in spite of chorionic elements found in the uterine curettings. In the first case microscopic examination of small nodules found in a surgically removed uterus and a small vulval nodule disclosed hemorrhagic necrosis, Langhans cells in large numbers, and no villous stroma. In the second case the uterus at autopsy showed extensive destruction of its tissue by large irregular masses of epithelial elements with extension into the vessels; the clinical history of this case was of postpartum hemorrhage. In the third case, curettings showed epithelial elements, syncytial cells, in

preponderance; the diagnosis of chorioepithelioma was refuted by the hysterectomy specimen which disclosed a normal uterus. The curettings were evidently only cells from a simple trophoblast.

It is concluded from these 10 cases that isolated chorionic cells per se are indicative only of a state of pregnancy, and that in large numbers they point merely to an abnormality of the uterus and not to increased independent activity of trophoblastic derivatives. The wide range, variations, and distribution of cell proliferation and infiltration makes the problem of deciding between malignancy or vigorously growing young trophoblasts a difficult problem for the pathologist, and necessitates careful correlation of these findings with the clinical history and hormone estimations. The presence of chorionic cell proliferations in (1) the last month of pregnancy, (2) after delivery, or (3) after expulsion or removal of a hydatidiform mole is generally indicative of malignancy; when they are seen early in pregnancy or in a still existing hydatidiform mole, the diagnosis of malignancy must be made with reservation. Finally, vaginal metastases are not necessarily malignant, and are benign when villous elements are also seen.

PHILIP B. CHASE, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY, AND URETER

Oddo, V. J.: Report of a Case of Acute Hemorrhagic Adrenallitis. *J. Urol.*, Balt., 1946, 55:1.

Oddo reports a case of unilateral hemorrhage into the adrenal gland in which the patient recovered following surgical measures. The disease has been described under different terms, such as the Waterhouse-Friederichsen syndrome, spontaneous suprarenal hemorrhage, and suprarenal apoplexy.

The patient was a white female, aged 36, who entered the hospital complaining of pain in the left upper quadrant and abdominal cramps for the preceding 2 weeks. The pains radiated to the left posterior renal region, the left scapula, and the vesical region, and were accompanied by nausea, vomiting, and frequency of urination. A moderate anemia was present. The urine contained many leucocytes and a few erythrocytes. Intravenous pyelography showed that the left kidney was enlarged and displaced downward; an abnormal soft tissue mass occupied the left upper posterior abdominal quadrant; the stomach was displaced to the right by an extrinsic mass in the same quadrant. Examination of the chest demonstrated the left diaphragm to be partially obliterated and elevated. It was smooth and regular. There was no evidence of metastatic disease in the lungs. Retrograde pyelography verified the previous findings. The temperature was septic in character. The patient suffered greatly from nausea, dyspnea, and pain, and as a result was losing weight rapidly.

Five weeks after admission laparotomy demonstrated a very large mass, smooth and tense, which had been palpable in the left upper quadrant of the abdomen. It extended upward as far as the tenth rib and downward to the crest of the ilium. The kidney could not be differentiated and appeared to be part of the tumor mass. Because of the position, immovability, and inaccessibility of the mass it was deemed better not to attempt its removal or even obtain a biopsy. The right kidney was palpable and not enlarged. The abdomen was closed and the patient left the hospital.

She was readmitted 18 days later, having lost 16 pounds and in much poorer condition. At the insistence of the patient a second operation was performed. The kidney could not be delineated. The tumor was tense, smooth, and appeared solid. After the perirenal fascia was opened, it was found that the kidney was situated below the tumor mass and was uninvolved. An incision was made into the mass for biopsy and more than a quart of dark liquid blood was obtained. After removal of a triangular section of the wall two cigaret drains were inserted into the tumor cavity, and the wound was closed.

The pathologist stated: "The specimen consists of an organized blood clot, connective tissue, and fat.

Some sections of the connective tissue element show cortical adrenal cells with deep staining nuclei and pale cells with granular protoplasm. The tissue was markedly infiltrated with leucocytes. Numerous thin walled blood vessels and nerve fibers were present."

Immediately following the operation the dyspnea quickly subsided, and the patient made an uneventful recovery.

DAVID ROSENBLUM, M.D.

Russl, S., Blumenthal, H. T., and Gray, S. H.: Small Adenomas of the Adrenal Cortex in Hypertension and Diabetes. *Arch. Int. M.*, 1945, 76: 284.

The authors have undertaken a study to determine whether or not small adrenocortical adenomas, encountered incidentally in the course of routine autopsies in persons showing no apparent evidence of endocrine dysfunction during life, could be implicated, in retrospect, in certain hormonal disturbances. In the course of 9,000 consecutive autopsies, 131 cases, an incidence of 1.45 per cent, exhibited these cortical adenomas. The incidence in males and females was approximately equal. The majority of adenomas occurred in persons more than 40 years of age, a peak occurring in the decade between 60 and 69 years. This, in general, corresponds with the age distribution in autopsies and may be significant.

The cortical cells of which the adenomas were comprised were of two types: (1) the predominant type, with a centrally or eccentrically placed hyperchromatic nucleus and cytoplasm filled with lipid vacuoles, and (2) a type with a centrally located nucleus, more vesicular than that seen in the first type, and cytoplasm either homogeneously eosinophilic or containing finely dispersed lipid droplets.

Analysis of the clinical data indicated that hypertension and diabetes were the only clinical conditions occurring with sufficient frequency in association with these small cortical adenomas to be warranted significant. Three levels of criteria for the determination of the existence of hypertension were used. On the basis of clinical data, the less critical criterion of blood pressure (140 systolic and 90 diastolic) indicated that there was an incidence of 70 per cent in the group with adenomas, as compared with 54.9 per cent in a general clinical group. The higher criterion of diastolic pressure in excess of 95 showed an incidence of 42 per cent, as compared with 22.4 per cent in the clinical group. The still more severe criterion, based on necropsy evidence of cardiac hypertrophy in the absence of contributory valvular or myocardial lesions, showed that 72.9 per cent of persons in the cortical adenoma group were hypertensive, as compared with 13.9 per cent in the general group examined at autopsy.

Among the 131 persons who exhibited cortical adenomas at autopsy, there were 21 with proved

diabetes, an incidence of 16 per cent. This is significantly higher than the 3 per cent incidence of diabetes in the entire autopsy group.

In the discussion of the apparent relation between cortical adenomas and hypertension, two possibilities, supported by experimental observations, are cited: (1) the adrenal hormones may render a person more sensitive to renin, or (2) they may be instrumental in producing changes in the kidneys which would lead to an increased renin production. It is generally agreed that certain adrenal cortical hormones increase the rate of glyconeogenesis and by this means increase the blood sugar level. The authors postulate that the increased incidence of diabetes in association with cortical adenomas derives from an increased production of cortical hormones.

In the discussion of the physiological roles of the two types of cells noted in the histological sections, the hypothesis is advanced that the vacuolated cells may well contain stored adrenal hormones, while the more solid cells are those in which the hormones are being discharged as rapidly as they are formed.

CLARENCE V. HODGES, M.D.

Duff, J., Kenyon, H. R., and Smith, K. F.: Malignant Hypertension; Neurosurgery of the Kidney. *J. Urol.*, Balt., 1946, 55: 153.

Establishment of the diagnosis of nephralgia is fraught with difficulty and a degree of uncertainty, but as an entity it certainly does obtain. The condition is characterized by intractable pain of kidney origin without demonstrable renal or ureteral pathological changes. It is, therefore, vital to exclude intrinsic kidney, pelvic, or ureteral disease. The most helpful differentially diagnostic sign, an observation emphasized by D. K. Rose, is the reproduction of the pain previously complained of by intentional distention of the renal pelvis. Pain thus elicited should reproduce precisely in location and radiation the patient's original complaint.

The operative technique for relief of nephralgia requires identification of the sympathetic nerve fibers and renal ganglion on the posterior and lateral aspects of the renal artery. They can be easily elevated with forceps and severed with scissors.

The renal artery is also denervated when judiciously possible, in conjunction with nephropexy, pyeloplasty, and nephrectomy.

The experimental and clinical researches of the past few years have focused our interest in the problem of hypertension. Whereas formerly the urologic surgeon was primarily concerned with controlling the effects of high blood pressure and its complications in patients under treatment for obvious urinary or genital disorders, we have, of late, approached the greater problem of underlying, causative factors in the development of hypertension, especially in relation to the kidneys, their blood supply, and neurological dysfunctions.

Of such patients coming under urologic supervision, four main categories can be defined: (1) those

with known urinary tract disease and concomitant hypertension; (2) hypertensive patients with asymptomatic disease of the urinary organs; (3) a miscellaneous group presenting endocrine lesions associated with elevation of the blood pressure; and (4) essential hypertensives.

All cases of hypertension are by no means malignant. Many are relieved and the individuals live comfortably for years under medical and physiotherapeutic regimes. Malignant hypertension is as yet a disease of unknown origin.

However, if the kidney is not the site of origin in malignant hypertension, at any rate it is the vital center of symptomatic projection; but further research may show the kidney to be the "victim rather than the culprit."

Malignant or essential hypertension at present can be most successfully relieved by surgery. Estimation of renal function and evaluation of the structural integrity of the kidneys are among the more important preoperative diagnostic procedures, and as the surgical approach is retroperitoneal, the operation should include exploration of the adrenal gland and biopsy of the kidney. It is, therefore, evident that the urologic surgeon possesses fundamental advantages in this field of surgery. The selection of cases and decision for operation requires thorough examination and classification.

Co-operation of competent consultants in the various specialties concerned is of utmost importance. Complete data regarding (a) eye grounds, (b) kidney function, and (c) electrocardiographic studies are essential to the diagnosis and prognosis.

In contradistinction to peripheral vascular diseases, the degree and severity of hypertension in essential hypertensives cannot be accurately determined preoperatively by nerve block.

Excretory urography is of value not only as an indicator of kidney function, but may be indicative of renal blood flow. It was observed that the dye should normally be excreted in about 55 minutes. If a roentgenographic shadow is demonstrable in the kidney pelvis after an hour, without obstructive uropathy, it can be assumed that the renal blood flow is impaired, provided that nephritis and nephrosis have been excluded.

Retrograde pyelographic studies, if not contraindicated, and kidney function tests, should precede all operations for malignant hypertension.

It is interesting to note that, following successful thoracolumbar sympathectomy, a most unpromising preoperative T-wave electrocardiogram report may be completely reversed.

The operation is bilateral and is performed in two stages, right and left. The first, second, and possibly the third lumbar ganglia, the ganglionic chain from the seventh to and including the twelfth thoracic ganglion, the greater, lesser, and least splanchnic nerves on each side are identified, dissected, and removed.

Observations by the authors and others working in this field indicate that following the Smithwick

sympathectomy abnormal renal blood pressures and ocular and cardiac findings present before operation show marked improvement. JOHN A. LOEF, M.D.

Dodson, A. I.: Some Improvements in the Technique of Ureterocystostomy. *J. Urol.*, Balt., 1946, 55: 225.

The urologist's experience with ureterocystostomy has, in the past, been confined usually to the reimplantation of the ureter, following its excision in cases of carcinoma of the bladder or in disease of the distal end of the ureter. The treatment of injuries resulting from pelvic surgery has in most cases been done by the surgeon or gynecologist responsible for the injury. However, in recent years the urologist has been called on more frequently to assist in the treatment of these patients.

The technique of the operation used will vary according to the problems met and, to some extent, according to the preference of the surgeon. The ureter can be transplanted successfully either transperitoneally or retroperitoneally. In the transperitoneal operation the peritoneum should be ac-

curately sutured over the ureter and extraperitoneal drainage should be provided to the area of implantation. Transperitoneal implantation is the natural procedure when an injury of the ureter is discovered at the time of a pelvic operation. When the operation is done only to reimplant the ureter into the bladder, the extraperitoneal approach has several advantages. The ureter is more easily exposed and liberated. Both the ureter and the portion of the bladder presenting the most desirable location for reimplantation are normally extraperitoneal. Retroperitoneal drainage is more easily instituted and there is less danger of disastrous results from leakage or infection.

Several writers have called attention to the value of mobilizing the bladder to decrease the tension at the point of union, and Kelly advised suturing the mobilized bladder to the pelvic wall to prevent tugging on the line of sutures by muscular contraction.

No one has, to the author's knowledge, mentioned the advantage of mobilizing or straightening the ureter to lengthen it and so lessen the distance that

Fig. 1. The incision has been made in the bladder wall, exposing the mucosa which is incised at the lower angle of the wound. A small catheter tied in the beveled ureter and sutured to the end of a catheter drawn from the bladder is being pulled out through the urethra. Ligation around the upper ureter interferes with drainage around the catheter and should be omitted.

Fig. 2. The ureteral catheter, having been pulled through the urethra, serves as a splint to the ureter and for drainage from the ureter and bladder

it must traverse to reach the bladder. The additional length of ureter made available by this procedure is considerable. This is true particularly when the ureter has become dilated and tortuous because of partial obstruction which often occurs following disease or fistula at the lower end of the ureter. Too, the ureter describes a considerable arc as it curves outward and backward along the surface of the true pelvis. This arc can be straightened to a considerable extent without interference with the physiology of the ureter. The abundant blood supply and the free anastomosis of the ureteral blood vessels make it possible to free the ureter almost completely without danger of necrosis. The ureter is only endangered when the loose fibrous coat is stripped

away. The author has found it necessary to ligate a small bleeding vessel at the end of the ureter before transplanting it when the ureter has been completely liberated well above the brim of the true pelvis.

The following is a description of the operation which, in the hands of the author, has given the most satisfactory results:

An incision is made, beginning just above and about 2 inches medial to the anterior spine of the ilium, and extending downward and inward parallel to Poupart's ligament. It ends in the midline of the abdomen, just above the pubis. The aponeurosis of the external oblique muscle is split throughout the length of the incision. The internal oblique and transversalis muscles are divided in the direction of

Fig. 3. Left, Mattress sutures fix the ureter in place; right, the muscles and fibrous coat of the bladder are closed over the ureter.

their fibers near the margin of the rectus muscle, just below the level of the anterior superior spine of the ilium. The fused aponeurosis of these muscles is then cut just external to the margin of the rectus down to the pubis. This gives room for wide exposure of the retroperitoneal area. The peritoneum is then separated from the posterior abdominal wall by blunt dissection from above the brim of the pelvis down to the bladder and medially to the spine. As the peritoneum is retracted medially, the iliac vessels are exposed and the ureter can be seen as it passes over these vessels and can be traced along the posterior surface of the peritoneum until it enters the bladder or disappears into a mass of adhesions surrounding a ureteral fistula. The ureter is freed from the peritoneum, from well above the iliac vessels downward to the fistula, or in ureteral disease, to the bladder. In the female, if the ovarian vessels interfere with liberation and exposure of the lower end of the ureter, they may be ligated and divided. The ureter is then divided just above the fistula or the diseased area. The lower segment is ligated or excised according to indications.

An incision is then made in the posterior wall of the bladder, extending from above downward, about an inch long, and as near the original ureteral entrance as possible. The incision extends to, but not through, the mucosa, which is carefully dissected from the bladder muscles for a short distance on both sides of the incision. The mucous membrane of the bladder is then incised at the lower end of the incision, and the end of a catheter, previously passed through the urethra, is grasped and pulled through the incision. The end of the ureter is beveled and a small, soft rubber catheter, which has had its end cut off and 2 small holes made in its sides near the end, is inserted into the ureter for 3 or 4 inches. A suture of plain catgut is passed through the tip of the beveled ureter and tied snugly to the catheter (Fig. 1). The catheter should not completely fill the lumen of the ureter. Two more holes are made in the catheter about an inch below the end of the ureter. The distal end of this catheter is then sutured to the tip of the bladder catheter, which is withdrawn, and the end of the catheter in the ureter is pulled out through the urethra (Fig. 2).

Fixation sutures are taken through the superficial tissues of the ureter on each side about an inch from the beveled tip. Both ends of these sutures are threaded on a small curved needle. The point of the needle is passed through the incision and the bladder wall from within outward. As traction is made on the catheter, the ureter is pulled into the bladder until the area pierced by the sutures enters the bladder incision. The sutures are drawn taut and tied on the outside of the bladder as mattress sutures (Fig. 3). The muscle and fascia of the bladder are fastened over the ureter from below upward with a continuous suture of chromic catgut (Fig. 4). The last suture should catch a small piece of the superficial tissue of the ureter. A small rubber tissue drain is carried down to the implantation and

Fig. 4 Completed implantation.

brought out near the upper angle of the wound. A mushroom catheter is then inserted into the anterior bladder wall through a short incision and a purse string suture is placed around the catheter, to make a water tight closure. The catheter is brought out at the lower angle of the wound. With the small catheter in the urethra and the large catheter placed suprapubically, complete drainage and absolute immobilization are assured. When the length of the ureter does not permit a submucous implantation, the operation differs only in that the ureter enters the bladder through a short incision directly through the bladder wall.

In addition to a summary of the viewpoints of numerous urologists on the techniques in vogue for the performance of ureterocystostomy, the article also includes 2 case histories illustrating the indications for surgical intervention and the results obtained from this operation.

BLADDER, URETHRA, AND PENIS

Mahoney, J. F., Blum, H. L., Van Slyke, C. J., and Cutler, J. C.: Experimental Gonococcal Urethritis in Human Volunteers. *Am J Syph*, 1946, 30, 1.

The authors report a study in the prophylaxis of gonorrhea employing human volunteers in a federal penitentiary. The study was terminated when it became evident that the principal objective probably could not be attained through the approach which was employed. Effort was made to develop a technique for disease production in volunteers which would be successful in the large majority of exposures. Two hundred and forty-one volunteers were employed. Each was given a financial reward and a certificate of participation. The ages ranged from 21 to 45 years. There was no evidence of pre-existing gonococcal infection; the urine sediment was negative on culture on three occasions (once after prostatic massage) prior to commencement of the study. There was no genital anatomical abnormality nor history of arthritis, but assurance of 6 months of postexposure observation availability. The volunteers were free of intercurrent disease or debility. They understood the purposes of the study, the risks involved, and were mentally acceptable.

Various infecting techniques were employed consisting in general of the instillation of 0.1 ml. or more of a suspension of gonococci into the navicular fossa, and, in certain instances massage, stretching, and engorgement of the glans and shaft of the penis. The technique was altered and varied as the experiment went on. None of the adaptations of the infecting technique employed was capable of producing disease in the uniform manner required to establish a prophylactic method. The general pattern of infections produced seemed to indicate that the constitutional resistance inherent in the individual volunteer is the factor which determines that an exposure technique, although successful in some members of the experimental group, may fail in others. The only exception occurred when direct transmission of the secretions from an infected patient to the urethra of a normal volunteer was done. Several instances of prolonged incubation were recorded.

In many patients, burning on urination occurred within the first 48 hours after inoculation. In some, a secondary urethral response, consisting of a culturally negative urethral discharge which occurred even weeks or months after inoculation, was observed. Commonly pain and tenderness of the vas deferens and/or epididymis, unilateral, bilateral, or alternating from side to side, was encountered. The authors termed this "vasosis" and "epididymosis." They believe that there was a spread of an irritant factor from the meatus to and through the vas deferens which caused vasosis and epididymosis. The presence of complement fixing antibodies seemed to indicate a minor degree of resistance to-

ward experimental infection. There was no instance of a persistent carrier state.

Sulfathiazole was administered for treatment and penicillin was given to sulfonamide resistant cases

GENITAL ORGANS

Kennaway, E. L., and Kennaway, N. M.: The Social Distribution of Cancer of the Scrotum and Cancer of the Penis. *Cancer Res.*, 1946, 6: 40

The authors tabulated 921 cases of cancer of the scrotum or of the penis according to the occupation of the patients, and came to the following conclusions:

The ratio of cancer of the scrotum to cancer of the penis is 1 to 20 in the agricultural workers, who are mostly agricultural laborers, and is nearly 3 times greater, or 1 to 2.6, in the nonagricultural laborers. Those engaged in lighter manual labor have a lower proportion of scrotal cancer than those performing the heaviest work. The clerical and light manual workers have a low ratio of scrotal cancer.

One case only of cancer of the scrotum occurred in England and Wales during a period of 30 years, in 17 occupations of the highest professional class. This 1 case was that of a person who in earlier life had belonged to a lower social class. The number of cases to be expected among the same number of persons, not especially exposed to carcinogenic materials, in the general population would be about 21. Hence it appears that this form of cancer could be eliminated by social factors. As cancer of the penis does not show this social distribution, these two types should not be pooled for statistical purposes. Data on the occurrence of cancer of the scrotum in native races and nonindustrial populations would be of great interest.

These two forms of cancer can be wholly eliminated: that of the penis by circumcision in infancy (but not in later life, according to the Moslem practice), and that of the scrotum through the conditions of life attainable by the richest classes

JOSEPH K. NARAT, M.D.

MISCELLANEOUS

Prather, G. C.: War Injuries of the Urinary Tract. *J. Urol.*, Balt., 1946, 55: 94.

Ten cases of injury of the urinary tract were observed in the Ashford General Hospital, in the Zone of the Interior, and the late results are described.

In 2 patients with penetrating wounds of the kidney and associated intra-abdominal wounds, transperitoneal nephrectomy had been performed at forward hospitals. In 2 of 3 cases of ureteral injury, late nephrectomy was necessary—in 1 patient for persistent fistula and in the other for calculus pyonephrosis. Two patients with rupture of the urinary bladder, and 1 patient with late perforation of the urinary bladder from a shell fragment, were treated by

suprapubic cystostomy. In 1 patient with multiple wounds of the thigh, scrotum, and leg, transection of the penile urethra was done. In this case there was also fracture of the right fibula and injury of the sciatic nerve. The urethra was successfully repaired 5 months after injury. In 1 patient with severe injury of the glans penis and distal urethra, fibrous atresia had developed and this was repaired by a plastic procedure.

The author states that although all of the definitive surgery and a good part of the reparative surgery in cases of this type has been completed before they reach the Zone of Interior, the facilities of rear echelons may sometimes be required for a detailed estimate of their final status. A named general hospital receives patients with injuries of this type for evaluation, further convalescence, and disposition.

FREDERICK R. LIEBERTHAL, M.D.

Kimbrough, J. C.: War Wounds of the Urogenital Tract. *J. Urol.*, Balt., 1946, 55: 179.

In the examination of 147 bodies of members of air crews killed in action, 9.5 per cent were found to have injuries of the genitourinary system in addition to other fatal wounds.

In the general hospitals on the continent, 235 consecutive wounds of the genitourinary system were treated from June to October of 1944. The kidney was involved in 14 per cent, the ureter in 3.4 per cent, the bladder in 14.5 per cent, and the external genitalia in 68.1 per cent of the patients.

Wounds of the kidney. In many cases the multiplicity of severe wounds makes complete urological examination impracticable. The urine of all patients with abdominal wounds should be examined. The presence of blood indicates injury to the genitourinary tract. Excretory urography may be used in field and evacuation hospitals, but its value is easily overrated. The function of damaged kidneys is usually suspended for several hours after injury, and the renal x-ray outline will not be present even in mild injury. Cystoscopy and retrograde urography are of doubtful value in field and evacuation hospitals because of the time required, and the trauma incident to instrumentation.

Thirty-three wounds of the kidney (14%) were observed. In 70 per cent, the only operative treatment required was that of the associated wounds. Nephrectomy was necessary in 24 per cent.

Wounds of the ureter. The diagnosis is often made at operation by the presence of urine in the wound. Urography, excretory and retrograde, is rarely practicable at the time of initial surgery. The low incidence of ureteral wounds reported is probably due to the fact that death from associated severe injuries usually occurs before the patients reach hospital facilities. Ureteral injuries should be repaired at the time of initial surgery. The ureter is sutured over a ureteral catheter which is left in place, and the urinary stream above the site of the injury is diverted. Massive scar tissue usually prevents ureteral repair at late operations.

Wounds of the bladder. The diagnosis is often made by a general physical examination and evaluation of associated wounds. Early diagnosis is imperative in avoiding a high mortality. Diagnostic urethral catheterization is very helpful. Digital rectal examination with the urethral catheter in place is a valuable procedure. Cystoscopy and the cystogram with air or opaque medium are usually not necessary in field and evacuation hospitals. If sufficient information is not obtained with these measures, exploratory operation is preferable to delay in cases of doubt. Further waste of time in determining if the wound is extraperitoneal or intraperitoneal should also be avoided because this can be ascertained at operation. Early drainage by cystostomy is necessary. Catheter drainage alone is rarely satisfactory and is usually dangerous. Repair of the injury is desirable. The recognition and treatment of associated wounds of the bowel and ureter are essential. The bladder is rarely involved alone.

Wounds of the external genitalia. In 160 patients with wounds of the external genitalia, the urethra was involved in 34, the penis in 44, and the scrotum and testicles in 82. In urethral injuries, repair should be carried out as soon as practicable. The urgencies of combat may often limit early treatment to control of hemorrhage and the conservation of tissue. Later repair is complicated by scar tissue formation and the resulting deformity. In treating wounds of the scrotum and testis, control of hemorrhage and conservation of tissue are imperative. All testicular tissue must be saved. The only indication for the removal of the testis is complete destruction of the blood supply.

Neurogenic bladder. Neurogenic bladder results from injury to the brain, spinal cord, or the peripheral nerves supplying the bladder. The majority of cases are due to spinal cord lesions. The injury due to edema, hemorrhage, and other types of compression is usually mild, and the urinary retention is transient. Injuries to the brain are often followed by no more than transitory retention of from 2 to 3 days' duration. Lesions of the cervical cord and upper dorsal cord offer a fair prognosis for establishing the so-called automatic bladder. Bladder dysfunction due to lesions of the lower dorsal and lumbar cord is more serious. Those due to involvement of the sacral cord are the most serious, and the patients rarely recover. As soon as the presence of a neurogenic bladder is determined, an inlying urethral catheter is inserted and tidal or other drainage is instituted. If the bladder does not show evidence of recovery in 4 weeks, a suprapubic cystostomy is performed, provided the patient's condition offers a reasonable life expectancy. The bladder should never be permitted to become overdistended. Spontaneous overflow, manual expression, and intermittent catheterization should be avoided strenuously. The catheter should not be left in place in the presence of severe infection. Early evidence of return of function, before any clinical signs of recovery

are evident, can be ascertained with the cystometer. Simple apparatus such as the water manometer is preferable. In the 193 cases reported by the author the bladder function did not return in 134. Cystostomy was performed in 130 of these. Catheter drainage, tidal and otherwise, was employed in 63 cases. Suprapubic cystostomy properly performed is the best standard procedure for general use by army surgeons. **FREDERICK R. LIEBERTHAL, M.D.**

Freid, J. R.: Skeletal and Pulmonary Metastases from Cancer of the Kidney, Prostate, and Bladder. *Am. J. Roentg.*, 1946, 55: 153.

The relative incidence of skeletal and pulmonary metastases from cancer of the urinary tract has been studied by the author in a series of cases coming to autopsy. The statistics obtained are compared with those cited in the literature dealing with this subject.

Of 87 cases of carcinoma of the kidney, 39 (45 per cent) showed skeletal metastases on roentgen or postmortem examination. The axial and trunk bones were more frequently involved than were the bones of the limbs. The lesions, multiple or single, were always destructive in character and rarely produced new bone.

Of 60 cases of carcinoma of the prostate, 35 (58 per cent) exhibited skeletal metastases. These lesions were essentially osteoplastic in character, but small areas of bone destruction were also generally present. In only 3 instances were purely osteoclastic changes observed.

Of 56 cases of carcinoma of the bladder, 6 (10 per cent) had spread to the skeleton, but in only 1 case were true metastases observed, the others repre-

sented invasion by direct extension from the primary tumor. In the cases of metastases cited in the literature, involvement was practically always osteoclastic.

Observations on irradiation therapy of bone metastases from carcinoma of the prostate and kidney indicate that little if any healing takes place following therapy and that the object of such treatment must be entirely that of palliation.

Of 87 cases of carcinoma of the kidney, 47 (54 per cent) showed pulmonary or pleural metastases. Parenchymal lesions were the most frequent and usually consisted of fairly large, sharply outlined nodules, most numerous in the lower two-thirds of the lungs. When pleural involvement was present, there was also usually an associated pleural effusion.

Of 60 cases of carcinoma of the prostate, 26 (43 per cent) presented intrathoracic extension of the disease. The most frequent finding was the association of pleural and pulmonary metastases.

Of 56 cases of carcinoma of the bladder, 4 (7 per cent) presented intrathoracic involvement.

Cough and dyspnea were the complaints most frequently complained of when pulmonary spread has occurred. Pain was next in frequency, and hemoptysis was rare. Irradiation was often ineffectual as a mode of therapy, usually because the patients were in such poor general condition that they could not tolerate the large dosages of radiation necessary for the relief of symptoms. Occasionally, however, relief of the cough and dyspnea and, when pleural effusions were present, slower refilling of the chest followed such treatment.

CLARENCE V. HODGES, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Greengard, J.: Acute Hematogenous Osteomyelitis in Infancy. *Med. Clin. N. America*, 1946, 30: 135.

Acute osteomyelitis in infancy has certain characteristics which are different from those seen in the older child and adult. In infancy, acute osteomyelitis is essentially a septicemia with localization in the bone, and in its management the blood stream infection and the primary portal of entry merit prime consideration. In infants as well as in older children, the infection in the bone starts in the metaphysis, but in infants there is a minimal amount of cortical bone at the metaphysis, so that spread to subperiosteal space is direct. The periosteum, more loosely attached at this age, is dissected from the cortical bone and the resultant subperiosteal abscess may rupture into the soft tissues without necrosis of the shaft.

The symptoms of acute hematogenous osteomyelitis in early infancy are variable. Two forms of the disease have been recognized in the newborn—one benign, the other severe. In the benign form there is usually no history of a preceding illness, and an area of swelling and dysfunction is noted over one of the long bones. On x-ray examination, an osteomyelitis is found which after several weeks or months undergoes resolution, without chronic disability as a rule. In the severe form the onset is usually early in the newborn period, with marked fever, often of a septic type. The concomitant symptoms will depend upon the primary disease which constitutes the portal of entry of the blood stream infection. In the newborn the umbilicus is a common site and evidences of omphalitis may be present with redness, induration, and a purulent discharge. Occasionally, a thrombophlebitis of the umbilical vessels may be present without external manifestations. The respiratory tract may not uncommonly be the source of septicemia in the newborn. Suppurative complications of an upper respiratory tract infection, such as an otitis media or sinusitis, may be present, or a definite pneumonia may be found. The skin or, less commonly perhaps, the urinary tract may be the site of a pyogenic infection which may result in septicemia. The bacteriology of these cases is quite variable: streptococci (nonhemolytic), staphylococci, pneumococci, or the pyogenic organisms may be found in the blood stream. The infection is severe, is often associated with icterus and hemorrhagic manifestations, and the mortality, even with modern therapy, is high. Localization in the bone occurs relatively late in the course of the illness and may be discovered in the course of routine x-ray examination, or may manifest itself by the formation of local soft tissue abscesses. The focus may be single, or multiple

areas may develop, and the bone lesion is more apt to become chronic with the development of sequestra and sinus formation, and, when large segments of bone are destroyed, as in the case of the head of a long bone, may result in chronic disability. However, the degree of restoration of the involved bone to normal is often surprising.

In the older infant the early symptomatology is also dominated by the septicemic symptoms. There is usually a sudden onset, often with high fever, and not uncommonly with respiratory tract symptoms. In a few instances a history of trauma to the area later involved is elicited. An infectious diarrhea or furunculosis of the skin may be the initiating symptom. After a few days the infant begins to show evidence of disability of an extremity, there is frequent crying, and soon it is noted that an extremity is held quietly in a position of rest. Passive motion of the extremity is painful, and at times tenderness over a metaphysis may be demonstrated. Careful examination of the adjacent joints reveals their free mobility. An enlargement of the metaphysis develops, and later a sense of deep fluctuation may be felt in this region. Usually, a soft tissue abscess develops and approaches the surface. In the acute stage, the infant is severely ill, and blood cultures usually contain organisms. X-ray evidence of bone destruction may be found in from 7 to 10 days after the onset. When localization in the soft tissue has become well developed, usually 2 or 3 weeks after the onset, the toxic manifestations tend to subside. If recovery from the acute septic phase occurs the prognosis is good. The bone lesion seldom becomes chronic and complete restoration to normal is the rule.

The treatment of acute hematogenous osteomyelitis in infancy may be divided into medical and surgical therapy. Medical therapy is concerned essentially with supportive measures to combat dehydration and toxemia, and specific chemotherapy aimed at destroying the invading organism. Surgical therapy is concerned with the management of the local bone involvement. Dehydration must be combated by the administration of parenteral fluid and blood, usually given by the intravenous route.

Penicillin is very effective against most of the organisms in acute hematogenous osteomyelitis, and it may be administered in a single large intravenous dose, followed by divided intramuscular doses at three hour intervals throughout the septic period. The individual dosage will depend upon the severity of the infection, 30,000 to 50,000 units being administered as an initial dose, and 5,000 to 20,000 units intramuscularly every 3 hours thereafter.

The sulfonamide drugs may be used either alone or in combination with penicillin. Sulfathiazole or sulfadiazine will be found to be the most effective and best tolerated. They must be used in large doses

and the usual precautions must be followed regarding their toxic effects. The author has found it advantageous to alternate the drugs in individual cases. As a general rule, from 0.1 to 0.2 gm. (1.5 to 3 gr.) per pound of body weight per day may be administered. When vomiting occurs, or the infant is very toxic, the sodium salt may be given intravenously. Most infants tolerate long continued chemotherapy very well.

Local therapy of the bone lesion consists in immobilization, local hot wet dressings, and the incision and drainage of soft tissue abscesses when they appear. Surgery to the bone should be held to an absolute minimum; incision of the periosteum over a subperiosteal abscess should usually constitute the maximum handling permissible. Local use of penicillin or sulfonamides may be of aid after incision.

The author reports a group of 10 cases of acute osteomyelitis in infants under 2 years of age, observed in the Children's Division at the Cook County Hospital, Chicago. This small series differs in some respects from the usual experience in osteomyelitis in young children. Eight of the infants were girls, while most reported series reveal a predominance among boys. The age of the infants varied from 2 weeks to 22 months.

The primary illness differed widely. Five of the 10 infants had some sort of involvement of the respiratory tract prior to the onset of the osteomyelitis.

Organisms were recovered from the blood in 6 cases, while in 4, blood cultures were negative. A staphylococcus albus was isolated in 4 cases, and in the remaining 2 cases staphylococcus aureus was found. In the experience of Green and Shannon, the streptococcus was more commonly found in infants.

The bones involved were a rib in 3 cases, the humerus in 3, the tibia in 2, and the femur in 1 case. There was multiple bone involvement (scapula, rib, and phalanx) in a newborn infant. Eight infants are progressing to complete healing of the bones involved. The sequelae in the other 2 infants were chronic osteomyelitis of the scapula and destruction of the humeral head, respectively.

Soft tissue abscesses were drained in 3 infants. Six infants were treated with sulfonamide drugs in varying amounts, from 6 gm. to 385 gm. Penicillin was used in 3 infants, the dosage varying from 560,000 units to 4,200,000 units.

There were no deaths in this series.

ERNEST E. ARNHEIM, M.D.

Hertzberg, J.: On Osteoarthritis Alkaptonuria (Ochronosis), with Description of a Case. *Acta radiol.*, Stockh., 1945, 26: 484.

Alkaptonuria with ochronosis is of clinical significance mainly because it occasionally produces joint lesions. They are caused by the deposition of ochronotic pigment in the joint cartilages, which become abnormally brittle and give rise to a specific kind of osteochondritis dissecans with loose body formation and synovitis (chondrosis dissecans

ochronotica). The gross roentgenological appearance of the joint lesions resembles that of deforming arthrosis.

The case of a 54 year old fisherman who complained of stiffness and pain in both shoulders for 2 years is presented. Alkaptonuria was discovered on admission. The principal roentgen findings were:

1. Osteoarthritis of both shoulders of a degree not seen in ordinary degenerative arthritis of the shoulders, characterized by large osteophytes, narrowing of the cartilage spaces, and rarefactions in the adjacent parts of the humeri.

2. Loose bodies, unusual width of the cartilage space between the femur and tibia, reduced width of the patellofemoral space, and subchondral sclerosis of the patella with osteophyte formation in both knees.

3. Osteoporosis and scoliosis of the spine with "patchy condensation" of the intervertebral discs.

A loose body was removed from the right knee together with a piece of the synovialis, to which it was adherent. The microscopic examination showed pigment in the bone spicules as well as in the surrounding connective tissues.

GERHART S. SCHWARTZ, M.D.

Bonner, W. L., and Baker, D. R.: The Diagnosis of Pes Planus with X-Rays. *Radiology*, 1946, 45: 36.

According to Hfeld, one-third of the men appearing before the C.D.D. Board of the Station Hospital at Camp Callan, California, came because of foot complaints.

In view of this very high incidence of foot disorders, the authors decided to carry out a systematic study on the possible roentgen diagnosis of pes planus and pronation of the foot.

In each instance a history of the case was taken first. Attention was paid to the various etiological factors such as heredity, especially through the paternal parent, static defects, infections, occupation, obesity, posture, and trauma.

The mechanism of pes planus is best understood by analyzing the effect of stress on the anatomic structures of the foot. Normally, the foot may be considered as an arch resting on two pillars. The anterior pillar corresponds to the heads of the metatarsals, the posterior pillar is represented by the os calcis, and the astragalus forms the keystone of the arch. Actually, there are two arches which meet in the subastragaloid articulation—the inner arch which serves the dynamic demand and the outer arch which controls side swaying movements. The axis of the joints of the foot are (1) the ankle joint, (2) the subastragaloid articulation, and (3) the 3 axes of the metatarsal joint. The principal joints involved in pes planus are the subastragaloid and midtarsal articulations. The deforming force consists of the rotatory component of upper pressure applied to the center of the ball of the foot. This results in rotation of the astragalus downward and inward, which causes flattening of the arch and convexity of the inner border, while the toes and meta-

Fig. 1. Roentgen measurement of the arch during repose.

Fig. 2. Roentgenogram of feet during weight bearing, double exposure technique.

tarsals rotate upward and outward. Thus the forefoot is in relative supination and dorsification as compared to the back part of the foot.

Pronation of the foot is, according to Morton, present when the body weight is concentrated upon the head of the second rather than of the first metatarsal. The criteria for diagnosis are: (1) elongation of the second metatarsal as compared with the first, (2) broadening of the shaft of the second metatarsal as compared with the fourth, (3) increased separation between the internal and middle cuneiforms, and (4) location of the sesamoids over the first metatarsal proximal to the head.

Flat feet and pronated feet may occur individually or they may coexist.

The roentgen technique devised by the authors is aimed at a study of both. For the first, lateral roentgenograms are made in repose (with the patient lying on the outer side of the leg) and during weight bearing (the patient standing on his foot and the film being exposed laterally). For the second, pedograms (foot prints) are taken in repose and during weight bearing, then the patient is stood on the film holder and an anteroposterior view of the foot is made by the double exposure method.

The position of the plantar arch and its deviation from normal is determined by measuring the distance from the base to the apex of the triangle formed by lines extending along the plantar aspect of the foot laterally. The base extends from the head of the

fifth metatarsal to the posterior plantar angle of the os calcis. The posterior side of the triangle connects the plantar eminences of the os calcis and the anterior side extending from the plantar aspect of the head of the fifth metatarsal through the plantar aspect of the proximal end of the fifth metatarsal (Fig. 1). The outer longitudinal arch of the foot is measured in this manner because of the greater simplicity. However, a comparison with the inner longitudinal arch in a certain number of cases shows that it represents just as true an indicator of the degree of involvement as the inner longitudinal arch.

After correlation with the clinical examination, the following figures (during weight bearing) were set up as indicative of the degree of pes planus: 1.0 cm. or above, normal; from 0.7 to 0.9 cm., first degree; from 0.4 to 0.6 cm., second degree; from 0.2 to 0.3 cm., third degree; and from 0.1 to 0.1 cm., fourth degree.

The pronation of the foot is determined on the basis of the enumerated criteria of Morton, as visualized on the pedograms and double exposure roentgenograms (Fig. 2).

Altogether the authors examined 400 subjects.

The findings in respect to pes planus were coordinated with the clinical findings. They are summarized in Table I.

The pronation studies gave the following results: Of the cases which appeared clinically and roentgenologically negative for pes planus, 57 per cent

TABLE I. COMPARISON OF
CLINICAL AND ROENTGEN FINDINGS

Clinical Diagnosis	Roentgen Diagnosis				
	Normal%	First Degree%	Second Degree%	Third Degree%	Fourth Degree%
Normal	17	24	37	16	6
First Degree	9	36	39	7	6
Second Degree	9	36	35	15	5
Third Degree	5	15	46	15	6

showed pronation on the films and pedograms. Sixty-five per cent of the cases diagnosed clinically as pes planus were negative for pes planus on roentgen examination but showed pronation. Of the cases with roentgen evidence of pronation, 61 per cent were negative for pes planus, 17 per cent showed first degree pes planus, 10 per cent second degree, and 5 per cent fourth degree.

It was further noted that the incidence of flat feet and pronated feet was higher among colored persons (90 per cent) than among whites (72 per cent), and that, contrary to the findings of other investigators, overweight of 10 pounds or more did not seem to be a factor in the incidence. T. LEUCUTIA, M.D.

Compere, E. L.: Flat Feet In Children. *Med Clin. N. America*, 1946, 30: 147.

This article attempts to place the proper emphasis upon the various foot ailments of children.

Many flat feet in children are normal and will stand as much hard usage as the feet with normal arches. Mild "pigeon toe" of children need usually cause no concern, for it means that the child is automatically going about the business of strengthening the arches of his feet.

Painful feet in children are not common. They may occur in arthritis, in chronic strain (which is seen in high arches more than in low ones), and in acute strains which may result from jumps or falls. The practice of keeping children's feet incased in stiff shoes results in the wasting of the intrinsic foot muscles until they no longer protect and support the various components of the foot.

The fundamental mechanics of the foot are discussed briefly, and it is pointed out that most of the common adult foot problems have their inception in childhood, especially if the intrinsic muscles are allowed to waste in unyielding shoes. The attempt to strengthen the muscles through exercises for a short period each day is termed mere "toe twiddling." Good oxfords and plenty of normal play activity are the best treatment for uncomplicated flexible, painless flatfeet, and children should be encouraged to play in their bare feet in good weather and on favorable terrain.

The recommended footwear is the oxford or sandal with strong leather soles, plenty of toe room, and lack of constriction of the circulation at the vamp.

The reinforced counter, extending forward to the scaphoid bone is advised. For the everted heel, a Thomas heel with an $\frac{1}{8}$ inch wedge on its inner side is suggested. If genu valgum is present the wedge should be $\frac{1}{4}$ inch high.

High top shoes, splinting of the ankle, and the prevention of normal development of the muscles, are referred to as a "vicious tradition." Metal plates are rarely required in these days when good orthopedic footwear is readily obtainable in retail stores. The acutely painful flatfoot, associated with marked disturbance in weightbearing alignment may require surgical treatment. Manipulation under anesthesia and the application of a walking plaster cast to maintain a position of inversion for from 3 to 6 weeks will suffice in a few cases, but in more severe cases arthrodesis of the midtarsal joints is indicated especially when anxious mothers, who become concerned about their children's feet through reading the lay magazines, may need more reassurance than their children with supposedly flat feet need treatment. Newton C. Mead, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Rose, T. F., and Newson, A.: Early Results of the Treatment of Gunshot Wounds of Limb Joints, Aided by Penicillin Therapy. *Med J. Australia*, 1946, 1: 75.

This article brings out the results obtained in the treatment of 66 gunshot wounds of the limb joints. The casualties were followed up for at least 5 weeks. The wounds are classified as: (1) those in which the capsule and synovial membrane only were involved. (2) those in which involvement of the capsule and synovial membrane, in addition to the bone ends, were damaged and there was a minimum cartilage loss and fragment displacement; and (3) those in which the joints were completely disorganized.

In this series there were 12 cases of the first type, 12 of the second, and 40 of the third. Blood serum and whole blood were given liberally. X-rays were taken routinely, if possible, before surgery. Pentothal was used for anesthesia routinely. When fluid or blood was aspirated from the joint cavity, penicillin was instilled. The patella was conserved if the articular surface was not impaired. In all operations upon the knee joint, 100,000 units of penicillin were instilled into the joint before the last capsular suture was tied. When it was impossible to close the joint, the wound was left open and gauze was packed down to the joint and soaked with 1:1,000 "monacrin" solution. This gauze was changed every third day until the joint could be closed. Intra-articular foreign bodies were localized and removed as soon as possible. When infected wounds were seen, or infected tissues were excised, penicillin was used liberally, both locally and parenterally. A 1:1,000 "monacrin" solution was used locally in all infected wounds. This antiseptic was efficacious not only against the pyogenic cocci but also against the bacilli

coli communis and, to a lesser extent, to the bacillus proteus. It has no effect on the pseudomonas pyocyaneus, but when this was present "monacrin" was combined with acetic acid (2%).

Immobilization was used according to routine methods, and the joints were made accessible through a window in the cast for treatment. Movement of these joints was commenced when compatible with the injury and the progress made.

The cases are discussed and the results obtained are listed. Four complete tables are presented, showing the joint involved, the treatment used, and the ultimate result. The infections are discussed. It is not inferred that the treatment used saved limbs and joints beyond a reasonable degree in view of the structural damage sustained; however, this method of treatment gave excellent results and many limbs and joints that otherwise may have been lost were made useful.

RICHARD J. BENNETT, JR., M.D.

FRACTURES AND DISLOCATIONS

Leveton, A.L.: March (Fatigue) Fractures of the Long Bones of the Lower Extremity and Pelvis
Am. J. Surg., 1946, 71: 222.

Twelve cases of march fracture of the long bones (exclusive of the metatarsals) and of the pelvic bones encountered during a 9 months' period in an army station hospital are reviewed in detail. The bones involved, in order of frequency, were the tibia (6 cases), the pelvis (3 cases), the femur (2 cases), and the fibula, (1 case). The author subscribes to the belief that these fractures are merely the response of the weight bearing skeletal frame to continuous overstrain.

There is a characteristic predilection of the site of these fractures. The tibias are usually fractured about 3 inches distal to the upper end, the fibulas generally fracture in the upper third or at the lower end, and the femurs are usually involved about 3 inches above the joint line or at the neck. The 6 tibial fractures occurred in healthy trainees 18 or 19 years of age.

The period of pain before hospitalization was quite prolonged, varying from 14 to 70 days. The symptoms began as vague pain chiefly referred to the knee, with muscle tenderness and stiffness, and bone tenderness in the upper third of the medial aspect. Later there was swelling with pitting edema and some increased heat and rubor. In general, the roentgenograms may be negative in the early stages but later there is usually some periosteal thickening on the medial and posterior aspects of the tibia. The fracture then tends to spread throughout the diameter of the bone as a crack in ice would spread. Old cases show an area of increased density in the area of the fracture. Complete fracture with displacement may result if march fractures are not protected until they are solidly healed.

Treatment may be carried out without casts or other immobilization if the patient remains at complete bed rest for from 8 to 12 weeks. Physical therapy is helpful in rehabilitation. In cases of march fracture of the femoral neck a double spica cast may be used to prevent coxa vara.

The pelvic march fractures, which show a predilection for the inferior ramus of the pubis, respond to bed rest until adduction spasm has subsided, then limited activity may be permitted until healing is complete.

NEWTON C. MEAB, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Naide, M., and Sayen, A.: *Venospasm. Its Part in Producing the Clinical Picture of Raynaud's Disease.* *Arch. Int. M.*, 1946, 77: 16.

The authors note that although many hundreds of papers have been written on Raynaud's disease, there is still no clear cut clinical concept of the mechanism involved nor an explanation for the varied pictures which are all classified under this term. The problem has been further complicated by the introduction of the term "Raynaud's phenomenon," since there is no agreement as to just what differentiates Raynaud's disease from Raynaud's phenomenon. Certain observations that have been made have raised the question whether arterial spasm can explain the entire picture of Raynaud's disease. These observations have made it possible to separate patients with the syndrome into several groups on the basis of their clinical behavior, and have added clarity to the diagnosis and treatment.

The author presents a classified group of venospasm disorders and a report in detail of 2 cases. The confusion that exists in interpreting the series of events in patients with Raynaud's disease and with Raynaud's phenomenon has arisen from failure to consider that the veins often partake in the pathological spasm.

A variety of pathological states are created by venospasm. The severe edema of thrombophlebitis is thought to be caused by the constriction of many veins in the extremity as a result of reflexes set up in the one segment of vein which is inflamed and in a state of irritability. It is also recognized that the venous congestion that occurs in thrombophlebitis initiates reflex arterial constriction. This is a necessary and useful reflex to prevent the continued swelling of the extremity which would occur if the arteries remained dilated, and it tends to prevent extreme edema when veins are obstructed or in spasm. Moreover, simply congesting the veins in one extremity causes widespread changes in tone of both arteries and veins in the contralateral as well as in the same extremity.

This impression was a basic factor in 2 patients with Raynaud's disease studied by the authors. The appearance of cyanosis and puffiness at the beginning of an attack in some patients suggests that venospasm occurs first, and that then, with distention of venules and capillaries distal to the spastic veins, reflex arterial constriction is initiated to prevent the swelling and congestion that would occur if the arteries remained unconstricted or dilated. An anatomic factor that fits into this concept of what may be happening in some patients with Raynaud's disease is that the veins in the hands are more superficially placed and are the first to be exposed to a stimulus such as cold.

In addition to an exaggerated constriction of veins and arteries from cold and emotional tension, as an explanation of the clinical picture in Raynaud's disease and in Raynaud's phenomenon, there is another factor that must be considered; that is, the possibility that in some of these patients the capacity for venous outflow is not as great as it should be in relation to the capacity for arterial inflow. It is possible that there may be an imbalance between arterial and venous flow. There is great variation in the caliber of veins in the hands and arms in different persons. Many of the patients with Raynaud's disease have small veins. A disproportion in the caliber of arteries and veins may in itself largely explain the cyanosis and puffiness. This is confirmed by the fact that cyanosis persists after sympathectomy in patients with Raynaud's disease, and may even increase.

A tendency to an exaggerated constriction of digital vessels is not uncommon. There is a tremendous range in vascular tone in the hands of normal persons. Failure to realize that there is also a wide range in abnormal digital constriction from cold and emotional tension has given an undeservedly serious connotation to the diagnosis of Raynaud's disease. The great majority of these persons have only mild symptoms, which do not increase in severity. It is only those with the severest grades of digital vasoconstriction who require sympathectomy. In the milder forms of Raynaud's spasm, reassurance is sufficient, together with mild vasodilator therapy. The authors have been impressed by the presence of factors that maintain a high degree of nervous tension in practically all patients with Raynaud's disease.

The program of management includes avoidance of exposure to severe cold, wearing of warmer clothing than that worn by the average person, taking of a warm tub bath daily in a warm bathroom, abstinence from tobacco, and use of an adequate diet. The use of thyroid substance is of value, since even a slightly reduced basal metabolic rate will aggravate a tendency to peripheral vasoconstriction in response to cold. Estrogen therapy is useful when Raynaud's disease occurs during the menopause.

In conclusion the authors state that their observation of 10 patients with Raynaud's disease and 4 patients with Raynaud's phenomenon revealed that spasm of the veins as well as of the arteries is present in the majority of these patients. Arterial spasm alone cannot explain the clinical picture in most patients. In some patients venospasm may predominate over arterial spasm. The clinical features in each patient will vary with the part of the vascular tree that is predominantly involved in the abnormal vasoconstriction.

In some patients with Raynaud's disease the clinical picture is influenced by an anatomic dispropor-

portion in capacity between arterial and venous flow. On the basis of clinical observations of these patients during the test for basal vascular tone, the authors present a classification to clarify the terms "Raynaud's disease" and "Raynaud's phenomenon."

Raynaud's disease is not rare. The milder forms are fairly common and do not deserve the connotation of seriousness usually associated with the diagnosis. Reassurance is an important part of treatment. In a patient with so called cold allergy, venospasm was found to develop on exposure to cold without development of arterial constriction, which explained the development of cyanosis and pronounced swelling without blanching. HERBERT F. THURSTON, M.D.

Kilbourne, E. D., and Wolff, H. G.: Cranial Arteritis; A Critical Evaluation of the Syndrome of "Temporal Arteritis," with the Report of a Case. *Ann. Int. M.*, 1946, 24: 1.

The syndrome heretofore designated as "temporal arteritis" is a well defined syndrome occurring in aged people of the white race. It was first described in 1932 by Horton, McGath, and Brown, and since that time 20 case reports have appeared in the literature. All but one of the patients studied presented signs and symptoms associated with infection; namely, anorexia, prostration, fever, sweats, weight loss, and leucocytosis, and locally, over the artery there was heat, swelling, tenderness, redness, and pain. The distribution of the pain and tenderness is indicative of preceding or concurrent inflammation of arteries of the lower half of the head. In half of the authors' patients, pain over the distribution of these arteries was primary. In more than half of the patients studied there was evidence of preceding or concomitant infection in the head, suggesting the possibility of spread of this infection by contiguity along the walls of the branches of the external carotid artery.

Differentiation of "temporal arteritis" from periarteritis nodosa cannot be made from the study of histopathological sections of the diseased arteries. Although in many cases of "temporal arteritis" giant cells are found, in some cases, eosinophilic infiltration, in the absence of giant cells, has occurred.

The authors give a very complete case study of a 63 year old man, and then give their concept of the etiology and pathogenesis of the syndrome. They believe that the term "temporal arteritis" is misleading, since it is probable that the disease involves other arteries of the head. Therefore, they propose the term "cranial arteritis" as the proper name for the syndrome heretofore known as "temporal arteritis." They feel that "cranial arteritis" is a much more definitive and inclusive descriptive title.

PAUL MERRELL, M.D.

Logue, R. B., and Mullins, F.: Polyarteritis Nodosa; Report of 11 Cases with a Review of the Recent Literature. *Ann. Int. M.*, 1946, 24: 11.

Polyarteritis nodosa is an obliterative, inflammatory, vascular disease involving the small arteries

and arterioles. The authors point out that the name periarteritis nodosa is an inadequate descriptive term since all coats of the vessel are involved. They believe that polyarteritis is a more exact name. The etiology is unknown. Pathological lesions are quite variable and it is obvious that their occurrence will depend upon the vessels involved in any given case. The tissues involved, in order of frequency, are: the kidneys (80%), the heart (60%), the liver (47%), the spleen, lungs, mesentery, peripheral nerves, the skin, and the brain. Three hundred and fifty cases had been reported up to 1942. Males are affected more than females, and the disease may occur at any age, the patients whose cases are reported being from 1 to 79 years old. Fifty per cent of the patients, however, are in the fourth and fifth decades of life. Cures are infrequent, the mortality rate being as high as from 90 to 95 per cent.

The symptomatology may be extremely variable and depend upon the tissues involved. The authors have worked out the percentages of some of the symptoms as they have occurred in the reported series of 177 cases. The laboratory findings revealed leucocytosis with a mild shift to the left in the active stages of the disease. A finding of eosinophiles is extremely variable. The sedimentation rate is commonly elevated. Anemia is common in the later stages. Hematuria and albuminuria are frequent.

While arteritis nodosa is of gradual onset, it may last for a period of months or years. The course of the disease may be punctuated by periods of remission and relapse.

The authors report 11 cases of their own (10 males and 1 female) with complete case histories. They point out that the duration of the illness varied from 2½ months to 1 year. One of their patients in whom the diagnosis of arteritis nodosa was made more than 2 years ago, is still living.

PAUL MERRELL, M.D.

Rosenstein, P.: New Findings with Respect to the Nature, Prevention, and Treatment of Thrombosis and Embolism (Novas pesquisas a respeito da natureza, da prevenção e do tratamento da trombose e da embolia). *Rev. brasil. med.*, 1945, 2: 734.

The author believes that with the knowledge now at hand a rational prophylaxis and treatment of thrombosis should be feasible, and should result in a reduction in the number of fatalities due to this condition. He omits all purely theoretical considerations in this field as not having as yet reached the stage which would be of value to the practitioner in medicine. The condition is of interest to all practicing physicians, since statistics show that fatal pulmonary embolism results almost as often from the thromboses arising in medical conditions, as in those following surgery and gynecological procedures. Of prime importance, of course, is the incidence of thrombosis in general, and it is particularly important to ascertain if the condition is on the increase.

BLOOD; TRANSFUSION

Simmons, R. T., Jakobowicz, R., and Kelsall, G. A.: The Rh Factor: A Survey of the Subtypes of White Australians. *Med. J. Australia*, 1945, 2: 493.

The Rh typing was performed by the authors in three different laboratories on 350 blood samples of groups O and A only. The blood specimens were not entirely a random sample of the two blood groups, as three families were included in the series.

The tests were carried out with anti Rh typing serum. The laboratory which used the American typing serum did 125 tests by the tube technique. The authors describe in detail the methods used in these examinations. The percentages of the results obtained were: Rh negative, 14.86; Rh^o, 54.0; Rh^{o'}, 12.57; Rh^{o'} Rh^{o''}, 16.57; Rh^o, 0.57; Rh^{o'}, 0.86; and Rh^{o'}, 0.57.

The authors note that recent figures for a total of 10,000 random samples of blood from Red Cross donors in Melbourne, tested with anti Rh^o and anti Rh^{o'}, Rh^{o'} serum, indicate that the blood of approximately 16.4 per cent of the persons tested was Rh negative. If anti Rh^{o'} serum had been used in the above Rh testing, the number of persons found whose blood contained the agglutinating Rh^{o'} would not have altered appreciably the Rh negative percentage of 16.4 per cent. An Rh negative percentage of 16.59 was found in a small series run in England. This was slightly higher than that found in a much larger sample. The Australian and English percentages, therefore, do not greatly differ, but are higher than the Rh negative percentage found in America for white persons.

Until recently the Rh^o antigen has been known as Rh, Rh_o, or the Rh factor; but after the discovery of Rh subtypes it was renamed Rh_o, or Rh^o, as Rh was taken to have a much wider meaning. This is the antigen common to the rhesus monkey and to about 85 per cent of white people. It appears to be the antigen responsible for the agglutinating antibody Rh^o, and for the blocking antibody which so far has been found to be specific against the Rh^o element in the erythrocytes. In whites it usually occurs in combination with another partial antigen, but uncombined, its occurrence in whites in New York City was 2.4 per cent, whereas the figure in England and Australia is under 1 per cent. It is found that among selected American negroes the percentage of Rh^o was as high as 41.6 per cent, and among unselected negroes, 24.5 per cent.

Occurring alone, Rh^{o'} is a rare subtype, but in combination with Rh^o it is found in 70 per cent of whites and was previously designated Rh₁; now, to avoid any ambiguity, and to be consistent with modern genetic terminology, it is named Rh^{o'}.

Rh^{o''} is a very rare subtype when occurring alone, but combined with Rh^o it is found in 30 per cent of whites; it was called Rh₂, and is now named Rh^{o''}. All of the three types, Rh_o, Rh^{o'} and Rh^{o''} react specifically with their corresponding antibodies.

In whites the Rh negative occurs in approximately 13 per cent of all persons, whereas in American negroes it is found in about 7.3 per cent. In other races it has been shown to be absent or very rare.

In conclusion, the authors state that the blocking antibody which has been recognized only recently, is of extreme importance. In the first place it cannot be detected by the usual agglutinating technique; secondly, it can exert a lethal effect upon the child of a mother whose serum contains it, and may cause hemolytic reactions from transfusion of apparently compatible blood; thirdly, it may occur together with the agglutinating antibody in the same person's serum and may mask the presence of the agglutinating antibody; and finally, it is regarded as having some effect in the prozone phenomenon.

In a high percentage of cases of hemolytic disease of the newborn, an agglutinating antibody can be demonstrated; but the blocking antibody will probably be found to be responsible for many of the remaining cases. The danger of the blocking antibody lies in the difficulty of its detection. For transfusion purposes crossmatching will not detect the blocking antibody, and its suspected presence will necessitate the full test. If blocking antibodies are present, no agglutination will occur, or the expected clumping will be much weakened. To appreciate the action of the blocking antibody, it can be regarded as an incomplete antibody, which in itself does not cause agglutination, but which places a protective coating on the cell to inhibit the action of the agglutinating anti Rh_o antibody. It should be noted that so far it has been found to be specific only in inhibiting anti Rh^{o'} agglutinating antibody, anti Rh^{o'} and anti Rh^{o''} antibody being unaffected by it.

The authors present briefly the technique of unmasking the presence of an agglutinating antibody in a specimen of serum suspected of containing both agglutinating and blocking antibodies. It is not clear whether the blocking antibody arises in response to the anti Rh_o antigen or whether it arises in response to immunization by a special antigen of its own. It is possible to make use of the specificity of the blocking antibody, which is anti Rh_o, by adding it to a strong polyvalent antiserum, for example, anti Rh_o, Rh^{o'} to mask the anti Rh_o agglutinin, leaving an active subtype anti Rh^{o'} serum. This is the method recommended for the preparation of monovalent subtype serum from polyvalent antiserum.

HERBERT F. THURSTON, M.D.

Callender, S., and Paykoc, Z. V.: Irregular Hemagglutinins after Transfusion. *Brit. M. J.*, 1946, 1: 119.

The development of irregular hemagglutinins, both as a result of isoimmunization in pregnancy and after repeated blood transfusions, is now well recognized, the familiar example being the immunization of the Rh-negative patient to an Rh-positive fetus or Rh-positive transfusion. During the past year, in an attempt to detect and identify such irregular agglu-

tinins, the authors have made a systematic study of 100 patients receiving transfusions. There were 52 women and 48 men in the series.

The majority of the patients were routine admissions to the medical wards, but one of the wards is associated with a research department, and a relatively high proportion of the patients in this ward suffered from blood diseases requiring repeated transfusions. Seven patients from nonmedical wards were also investigated, either because they had shown a transfusion reaction or because they were known to be Rh-negative. In all there were 37 cases of hematemesis; 14 of ulcerative colitis; 31 of blood dyscrasias, 7 of which were cases of aplastic anemia; 4 were healthy volunteers who were being bled and transfused for red cell survival experiments. The remaining 14 patients suffered from various conditions such as battle injuries, sepsis, and menorrhagia.

The authors discuss the methods they used in studying these patients from the standpoint of arteries, physical findings, blood groups, obstetrical history, and reactions. They report 3 cases, discuss the findings, and present their conclusions as follows:

Of 100 patients transfused with 958 pints (544.1) of blood, 2 patients were shown to have developed irregular agglutinins.

One Rh-negative patient developed anti-Rh (symbol) after a single transfusion without previous isoimmunization by pregnancy.

One Rh-positive patient developed St (γ Fisher) and 3 new antibodies, all active at 37° C.

Cold agglutinins were found in the sera of 88 of 95 patients examined, in titers of 1 to 128. In 15 of these the agglutinins were also active at room temperature.

In 2 patients an agglutinin was found which was active at 37° C and reacted with the patients' own cells only.

PAUL MERRELL, M.D.

Murphy, H. M.: The Transmission of Infectious Hepatitis by Blood Transfusion; A Report of 2 Cases. *Gastroenterology*, 1945, 5: 449.

Two cases of infectious hepatitis are reported following the transfusion of blood from donors who on the same day and the following day developed clinical symptoms of infectious hepatitis. The disease then was observed to develop in both recipients 24 and 47 days, respectively, following the transfusion. In the case showing the shorter incubation period, laboratory and physical findings were present from the seventeenth post-transfusion day although clinical symptoms (an abrupt rise in temperature, headache, and malaise) did not occur until the twenty-fourth day. The icteric index returned to normal in 7 weeks.

The second patient had received several other transfusions. Forty-five days after the transfusion only a slight elevation of the phosphatase was observed. Clinical symptoms (anorexia and nausea) occurred on the forty-seventh day. He then developed jaundice which persisted, although his systemic symptoms disappeared 2 days later. The duration of the disease was not known as the patient was evacuated.

As to the short incubation period in the first case, it was mentioned that he had been in Italy for several months and many cases of hepatitis had occurred in his organization, therefore he may have already had the disease at the time of the transfusion. The donor in this case died and therefore the virulence of the agent is also questionable.

The incubation period is discussed and the reports of several investigators are reviewed.

Prospective donors with a history of hepatitis should not be used. Accidents such as the 2 described are unavoidable when large numbers of transfusions are being given in an area where hepatitis is epidemic. THOMAS C. DOUGLASS, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

Robertson, K. C.: Postoperative Pulmonary Complications. *Edinburgh M. J.*, 1945, 52: 460.

Irritative conditions, e.g., acute tracheobronchitis, embolic manifestations, atelectatic phenomena, and acute pulmonary edema, are the most frequent postoperative pulmonary complications.

Among 1,890 cases of all gynecological types operated on during a 2 year period, only 20 developed pulmonary complications which were serious. Of this group of 20, 11 were cases of pulmonary embolism, 7 of acute bronchitis, 1 was empyema of a pneumococcal type, and 1 was pulmonary edema.

The average age for the development of pulmonary embolism was 47 years. The attack occurred on the tenth or eleventh postoperative day. The clinical features were typical. There was a premonitory increase in the pulse, temperature, and respiration, followed by pleural pain in the affected part. An early slight unproductive cough may appear before there is any complaint. The sputum was bloodstained in only 6 of the 11 cases. The possibility of the development of pneumonia in the affected area is fast disappearing because of the early use of sulfonamides.

Treatment is empirical. The pain must be allayed, the shock counteracted, and the general circulation improved, since some degree of cardiovascular insufficiency is present in most patients with pulmonary embolism.

Synthetic anticoagulants, like dicoumarin or dicoumarin plus heparin, must, in the future, play an important part in the prophylaxis of such ailments. Other preventive measures should include: (1) early active and passive movement on the part of the patient, as soon as consistent with comfort after the operation; (2) enforced hyperventilation of the lungs by deep breathing exercises; and (3) the reduction of the use of narcotics to a minimum.

Collapse of the lung occurs only when there is absolute bronchial occlusion; the more viscid the sputum, the greater is the tendency toward collapse. Since the unimpaired circulation of blood in the lungs is also an important factor in the production of collapse, the condition arises most frequently in young healthy adults. The clinical features of collapse are outstanding and dramatic in their suddenness, so that the diagnosis is not difficult. The differential diagnosis must be made from pulmonary embolism, lobar pneumonia, and spontaneous pneumothorax. In collapse, in addition to the local dullness, the mediastinal shift, and the absent or weak tubular breath sounds, the respiration is jerky, twitching, or spasmodic because of tonic irritative contractions of the diaphragm.

The treatment in collapse is to displace the plug of viscid mucus by simple postural coughing and by having the patient take deep breaths. Drugs are of little avail, but sulfonamides should be given prophylactically.

Acute pulmonary edema is due to the seepage of a serous transudate through not only the active capillary bed of the lungs but through the whole of the reserve capillary structure as well. The factors which play a part in the production of this condition are (1) hypoventilation with resultant lung rigidity, (2) impaired circulation, with consequent lack of proper oxygenation, and (3) a possible temporary reduction in the output of the left ventricle, which upsets the fine degree of balance existing between the two chambers of the heart, which is so essential for normal pulmonary circulation.

The treatment of pulmonary edema consists in the use of (1) oxygen, (2) venesection, (3) morphine, and (4) atropine. SAMUEL KANN, M.D.

Grandstaff, E. H.: A New Treatment for Postoperative Pulmonary Collapse. *Arch. Surg.*, 1945, 51: 237.

The author reviewed the records of postoperative pulmonary complications at the Kansas City General Hospital, Kansas City, Missouri, for a 2 year period and found that of 2,704 patients given an anesthetic, 6 developed massive pulmonary collapse, 15 atelectasis, and 51 pneumonia. All patients with collapse or atelectasis recovered quickly; 24 of those with pneumonia, in most of whom it was a terminal affair, died.

The causes of postoperative pulmonary collapse are discussed; among them are pain from the incision in abdominal operations, splinting of the lower intercostal muscles, interference with respiration by kidney rests, oral sepsis and acute or chronic infections of the respiratory tract, and excessive postoperative sedation. Two other factors are stressed. One is that failure to wait for premedication to take effect means starting the anesthetic before the maximum anhidrotic effect of atropine or scopolamine has been attained. The other factor is the anesthetic agent. Ether is irritating to the bronchial mucosa and stimulates the production of secretion. The oxygen-rich atmosphere behind an obstructing mucus plug is quickly absorbed, and leaves a small portion of collapsed lung. Cyclopropane produces very little bronchial irritation and less vomiting than ether, hence less possibility of aspiration.

Collapse occurs suddenly, a day or so after operation. It is characterized by chest pain, dyspnea, sharp rise in the temperature, pulse, and respiration. The physical findings are dullness over the affected side, absence of breath sounds, some fixation of the affected side of the chest, elevation of the diaphragm on the same side, and a shift of the area of cardiac

INTERNATIONAL ABSTRACTS OF SURGERY

83

hullness toward it. Sputum, at first scanty, soon becomes profuse and mucopurulent. The white count is between 15,000 and 20,000. The twenty-ninth gram is characteristic, showing narrowed intercostal spaces and an elevated diaphragm on the affected side, deviation of the heart shadow toward it, and a dense homogeneous lung.

Treatment is primarily prophylactic. Premedication should be closely correlated with the type of anesthetic to be given. Before the patient leaves the operating room he should be partially awake, at least to the extent that his pharyngeal reflex has been restored. After he has been returned to his bed, frequent changes of position, inhalations of carbon dioxide and oxygen, deep breathing exercises, and minimal sedation are important precautions.

However, when, in spite of precautions, collapse has occurred, the author has had complete success with a new method of therapy, which he describes. A cotton ball is soaked in from 5 to 10 per cent cocaine solution, held in a curved applicator, is placed far back in the throat and into the pyriform sinuses. This pledget, held in the bronchial tree sufficiently that as it is in preparation the patient coughs up the pledget, partially relaxes the bronchial tree sufficiently that within a few minutes the patient coughs up the offending mucus plug. The use of a little solution of epinephrine in the same pledget will stimulate the cough reflex. Voluntary attempts at coughing are to be encouraged. After the obstruction has been expelled, inhalations are given for at least 24 hours and the patient is given a set of blow bottles to insure continued aeration of the involved lung. If chemotherapy, sulfathiazole or sulfadiazine, is instituted at the time the diagnosis is made it helps to prevent the occurrence of pneumonia in the aureous congested lung. The author has had no failures with this method and hence has had no resort to the more formidable procedure of bronchoscopy.

H. F. LOEWENBERG, M.D.

Jacobi, M., Klein, B., Rascoff, H., and Kogut, H.: Effect of the Intravenous Administration of Oxygen on Shock in Dogs and in Human Beings. *Arch. Surg.*, 1945, 52, 42.

One hundred per cent oxygen has been reported to be beneficial in the treatment of shock. Reasoning from this report and the relatively small quantity of oxygen utilized when inhaled, the authors believed that oxygen could be given more efficiently intravenously. They believe that the previous discouraging reports were due to the use of too great a quantity, too rapid administration, or administration at too high a pressure.

Irreversible shock was produced in 12 dogs by the intravenous injection of a saline extract of dog muscle (Moon). Three of these dogs received no treatment and died in from 5 to 7 hours. Three more received between 300 and 500 c.c. of plasma and lived from 10 to 11 hours. All of them showed marked hemocoagulation. The remaining 6 dogs were treated by oxygen given intravenously, by means of a modified apparatus described by Langer.

at the rate of 100 c.c. per hour. Treatment was stopped prematurely on one dog; a relapse and death followed. The 5 other dogs were treated from 15 to 24 hours with reduction in hemocoagulation and recovery. At autopsy no evidence of air embolism was noted.

Three cases of severe shock are reported in patients in whom all the usual methods of treatment had failed. The intravenous injection of oxygen then resulted in prompt recovery of all 3. One of these patients had been subjected to a difficult subtotal resection for an advanced carcinoma of the stomach. In this case oxygen was given at the rate of 600 c.c. per hour and was continued for 30 hours.

The 2 other cases reported were severe birth injuries which appeared to be hopeless as neither responded to the usual therapeutic measures. Response to 900 c.c. of oxygen per hour in one and to 700 c.c. per hour in the other was prompt and dramatic, in 2 minutes in the first case and in 15 minutes in the second case. The first baby died 3 weeks later of a pneumococcal meningitis. The second died 3 days postpartum of a subdural hematoma. Neither showed any evidence of air embolism.

THOMAS C. DOUGLASS, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Rawles, D. W., Jr.: Repair of Soft Tissue Wounds. *Ann. Surg.*, 1945, 121, 709.

The author states that from 85 to 90 per cent of uncomplicated soft tissue wounds can be closed successfully in from 4 to 10 days after adequate debridement. This policy of early closure was generally adopted in the winter of 1913-14. At first, complicated wounds were so treated, but later, with penicillin and blood replacement, extensive and even complicated wounds were closed. The present principles have been reported by Churchill. The present article deals with the experiences of a general hospital in this theatre.

The goal of early closure is to create a closed wound so that men may be returned to duty earlier, or so that reconstructive surgery may be accomplished sooner.

Repair may be undertaken (a) early (4 to 10 days), (b) late (after 10 days), and (c) by a planned stage method to be described. Wounds may be closed by (1) approximation of skin edges, (2) skin grafts, (3) simple plastic procedures, and (4) combinations of the three.

Early repair is more successful because of the low incidence of infection, ease of accomplishment, and minimal scar tissue formation. Contraindications to early closure are evidences of frank infection. Infected cases were allowed to "clean up" (1) with moist resilient pressure dressings, and (2) removal of devitalized tissue and drainage of pus pockets, followed by repair in 4 to 6 days after penicillin

therapy and blood replacement, if necessary. The original dressing, which was applied following débridement, was usually not changed until repair was attempted.

Of some 601 wounds in 422 battle casualties, 391 were closed early (in less than 12 days) and 300 late (over 12 days). In the first group, 94.6 per cent healed almost per primam; in the group closed late, 60 were closed by simple approximation, 61.7 per cent healing per primam; and 240 were either partially or totally excised before closure, 75 per cent of them healing per primam.

Patients with soft tissue wounds usually reached the general hospital on from the third to the fifth day, and their wounds were closed as soon as possible after temperature, blood, and x-ray studies could be made, and the fatigue of travel had been relieved by rest. Blood was replaced when indicated. Clinical judgment rather than bacterial studies determined whether the wound should be closed, since the authors knew they were contaminated, and further delay occasioned by cultures would have carried these wounds past the optimum time for closure.

Intravenous sodium pentothal was used in most cases, but in patients whose repairs extended over a period of more than 30 minutes, nitrous oxide ether inhalation anesthesia was administered. Blood clots, if present, were carefully removed; foreign bodies were removed only if readily accessible, or if it was thought they would interfere with vital structures. Most wounds were closed by simple approximation of the skin edges. After a few days, wound edges have a tendency to curl down, and in cases in which this occurred, they were gently freed with a blunt instrument before closure.

When wounds are closed early, moderate tension may be used because as soon as the wound is closed the edema subsides and the tension lessens before any strangulation of incorporated tissue can take place. An attempt was made to encompass the wound to eliminate dead space. Drainage was employed only rarely, when deep pockets could not be obliterated or when there was profuse drainage from a long perforating wound, in which cases rubber tissue was used.

Skin grafting was employed when the wound edges could not be approximated. Split-skin grafts were used in preference to rotation or advancement. Complicated plastic procedures are best undertaken after wounds have healed, and here again resilient pressure dressings were used.

Closure after the tenth day was not by choice, but was occasioned by late evacuation, as in chest and abdominal wounds, or by other complications such as infection. In small wounds excision was best, whereas, in the larger ones excision of the wound edges, with undercutting and approximation by suture or graft, was done. Less success could be expected in these late cases.

In the planned stage method, some of the wounds, because of infection or the presence of devitalized tissue, were secondarily débrided and then closed 5

days later under protection of penicillin and blood replacement. Resilient pressure dressings and splinting of adjacent joints were essential to good healing. Penicillin was a valuable adjunct to successful reparative surgery and, particularly, a safeguard against clostridial myositis.

Early intensive mental and physical reconditioning was necessary if men were to be returned to combat.

BYROND F. HICKETT, M.D.

Hamrick, W. H.: Suture of the Fingernail in Crushing Injuries. *U. S. Nav. M. Bull.*, 1946, 46: 225.

In certain injuries of the finger tip, when the nail root has been avulsed but the distal part of the nail remains partially attached to its bed, the remaining portion of the nail may be utilized as a protective covering by suturing directly through the nail. A typical injury for which this method of treatment can be employed to advantage consists of avulsion of the nail root, with the distal three-fourths of the nail partly attached and the phalanx fractured. The trauma is usually caused by the sharp edge of a slammed window, car door, or frequently by a cutting tool in industry. A palmar bridge of soft tissue is often all that remains of what was almost a complete amputation.

Block anesthesia is secured at the base of the finger, which is then cleansed thoroughly with ether, green soap, and sterile saline solution. Hemostasis is effected temporarily by small hemostats after initial débridement. The nail root is transected with a scissors, and the proximal edge of the remaining distal attached nail is trimmed to fit the curvature of the eponychium. In most cases the distal fragment of bone is removed by sharp dissection, but if the palmar skin bridge is so small as to make the blood supply questionable, the chips are left in. Union rarely occurs, but this appears to offer no inconvenience. The epidermis of the distal wound edge is trimmed so that none of it overhangs. With non-absorbable suture material of about 000 size on a small curved cutting needle, 2 vertical mattress sutures are placed through the nail and proximal wound edge. Similar deep mattress sutures are placed in the soft tissues on either side to obtain perfect apposition and to close all dead space. A dry dressing and finger splint are applied over a sterile strip of cellophane, which prevents sticking. Redressings are infrequent, and the sutures are not removed until the tenth day. The remaining nail becomes completely detached within a few weeks, and the new nail grows out firmly attached at the root and to most of the peripheral nail bed.

JOHN L. LINDQUIST, M.D.

Le Quesne, L. P.: Bacteriology of Septic Fingers. *Brit. M. J.*, 1946, 1: 163.

A study was made of the primary organism and the secondary invaders in a consecutive series of septic lesions of the hand which required incision in an out-patient department. None was severe enough to warrant admission to the wards. The surgeon did

not wear a mask, and used ungloved hands. The dressings were changed by a student or nurse, using the fingers, and at times the nurses passed from case to case without washing their hands.

A swab was taken from the lesion at the time of making the incision, and further swabs, so far as possible, were taken at two-day intervals until the finger was healed.

In a series of 100 cases which were fully investigated, the staphylococcus aureus was isolated from 93 per cent of the cases, and *B. hemolytic streptococcus* from 5 per cent. Eighteen patients became secondarily infected (4 of them with two organisms) before healing occurred. Thus, on 22 occasions a secondarily infected organism was isolated, but of the 22 organisms, 14 were recovered on one occasion only. In none of the 4 doubly infected cases were both organisms isolated more than once. Therefore, in only 8 cases did secondary infection become established. In 3 cases the secondary invader was the hemolytic streptococcus, in 3 it was the staphylococcus aureus, and in the remaining 2 it was the staphylococcus albus.

The average time between incision and healing in cases which did not develop secondary infection was 11.12 days; in those developing such infection, 20.88 days. Because of the small number of cases studied, the author does not consider these figures significant.

The author suggests that the actual incidence of secondary infection may have been higher than the figures given because of the inability to distinguish one strain of staphylococcus aureus from another. He believes that this rate can be materially reduced by a rigid aseptic technique and the intelligent use of wound antiseptics. THEODORE B. MASSLE, M.D.

Altemeler, W. A.: Penicillin in Tetanus. *J. Am. M. Ass.*, 1946, 130: 67.

Tetanus, or lockjaw, is one of the most dreaded infectious complications of wounds. Its treatment is still unsatisfactory and the results uncertain, even though its etiology has been known for 60 years and its diagnosis is relatively easy. The failure of large doses of antitetanic serum to alter the course or lower the mortality once the disease has developed is disappointing. This is true particularly in cases in which the incubation period is less than 6 days. Firor states that the outlook of generalized tetanus is always grave, and the mortality rate is frequently determined before the patient is seen by the physician. In one group of cases, no form of therapy known at this time will prevent a fatal outcome, while in another group—cases seen during the prodromal period—the recovery depends on early diagnosis and adequate treatment. This is a report of the potential value of penicillin in the management of established tetanus.

The author during the past 23 months has treated 16 cases of established generalized tetanus. Eleven of the patients were under 10 years of age and the oldest was 32 years old. Eleven were males and 5 females. The portal of entry was usually so small

that it was frequently overlooked. In 2 cases the primary wound was unknown and never demonstrated. Five wounds were puncture wounds. Four were infected lacerations, 3 were abrasions, 1 was a plastic operative wound, and 1 a recurrent foot ulcer. Ten patients had wounds of the lower extremity; 2 had wounds on the face, and 2 had wounds on the hand. The incubation period was unknown in 3 cases, less than 5 days in another 3, from 6 to 10 days in 6, and from 11 to 15 days in the last 4 cases.

All patients received antitetanic serum, intravenously or intramuscularly, as soon as the diagnosis was made. The amount given varied from 20,000 to 390,000 units. Fourteen of the patients received 50,000 or more units, 10 received 100,000 or more, and 5 received 250,000 or more units. In 9 cases the primary wound was excised an hour after from 10,000 to 20,000 units of antitetanic serum were infiltrated into the surrounding area. The wounds were left open and packed with zinc calcium peroxide ointment. Thirteen of the patients received penicillin in dosages of 15,000 units every 3 hours. In 8 cases a total of 500,000 or more units were given, and in 3 cases from 1,000,000 to 1,500,000 units were given. It was intended to give all of the patients a total of 1,000,000 or more units of penicillin if they had lived long enough.

In this series there were 10 deaths, a mortality of 62.5 per cent. Nine of the 13 patients receiving penicillin died. All the patients with an incubation period of 5 days or less died, 4 of 6 with incubation periods of from 6 to 10 days died, and only 1 of 4 with incubation periods of from 11 to 15 days died. Two of the 3 with unknown incubation periods died. Their clinical courses suggested that their incubation period was 5 or 6 days or less. These observations bear out the relationship of high mortality rate and short incubation period.

The amount of antitoxin given did not seem to affect the survival rate. Four of 5 patients receiving 250,000 units or more died, 5 of 10 receiving 150,000 units or less died, and 4 of 6 receiving 75,000 units or less died. Only 1 case of typical serum sickness developed.

Clinical improvement in most established infections usually occurs in from 18 to 72 hours after the onset of treatment with penicillin. In these cases of tetanus treated with penicillin, no obvious beneficial results that could be attributed to the penicillin were noted except in 1 case which had a complicating pneumonia. Six of the 9 deaths following penicillin treatment occurred within 60 hours after admission and the beginning of treatment. These were due chiefly to respiratory arrest associated with toxemia, pulmonary edema, and hyperpyrexia.

The author then gives reports of 5 cases in 4 of which the patient recovered. The purpose of these reports was to illustrate the results of special interest. To control convulsions the author used phenobarbital sodium, paraldehyde, tribromethanol, and pentothal sodium.

In the author's experience, penicillin has not proved to be a lifesaving measure in treating tetanus as reported in the literature.

Tetanus is an infectious disease developing after a variable incubation period and caused by a potent water soluble toxin produced in a wound infected by clostridium tetani. The wound is usually small, probably because most large wounds have medical care and are given 1 or more injections of antitoxin routinely. There is no problem of local invasiveness or tissue destruction in these wounds as in other types of infections. Instead, it is the production, distribution, and fixation in susceptible tissues of extremely small quantities of a specific and powerful toxin. After a fatal dose of toxin has become fixed in the central nervous system, death is inevitable, as the antitetanic serum, even in extremely large doses, fails to affect the course of the disease. This is a sharp contrast to the effectiveness of only 1500 units as a prophylactic preventative at the time of injury.

Penicillin, although effective against clostridium tetani, has no known effect on its toxin. Therefore, the results of this series were not surprising. Complications such as pneumonia or secondary invasive wound infection during the course of tetanus are well treated by the use of penicillin.

The failure of penicillin to alter appreciably the course of established generalized tetanus re-emphasizes several important concepts: (1) the length of the incubation period is the most important single prognostic sign; (2) the essential primary cause of the disease is a bacterial toxin; and (3) successful management depends not on chemotherapy, but on early diagnosis during the prodromal period with immediate neutralization of the existing free toxin by serotherapy, removal of the source of toxin, control of the convulsive seizures, control of attacks of respiratory arrest, and the administration of general supportive measures.

ROBERT R. BIGELOW, M.D.

ANESTHESIA

Mousel, L. H., Stubbs, D., and Kreiselman, J.: Anesthetic Complications and Their Management. *Anesthesiology*, 1946, 7: 69.

Anesthesia complications are essentially deviations from the normal physiology. The extent and the duration of these deviations will determine whether death occurs or whether the incident becomes a postoperative complication. Anoxia plays a most important part in these complications.

This report is a detailed study of 47 deaths under anesthesia occurring in the Washington area, with an incidence of from 1 in 300 cases to 1 in 8,000 cases. The range of variation was dependent upon the skill and training of the anesthetists involved. Most anesthetic deaths were caused by the improper selection of anesthetic agents, improper administration, improper replacement therapy, or failure to do efficient resuscitation.

The differential mortality was highly unfavorable to cyclopropane. In more than half of the cases in which death occurred during the administration of this agent, primary or at least very early cardiac failure was observed. Death occurred from 20 to 25 times as frequently in hospitals with the poorest types of anesthetic organization as in those institutions with highly trained specialized anesthetists. Nitrous oxide was considered a hazardous agent when even mild oxygen want was present, and primary and secondary saturation methods of administering gas were severely condemned. Reliance upon the suck and blow method of resuscitation and upon the so-called analeptic or respiratory stimulants was considered a serious mistake; nor has carbon dioxide a place in the treatment of asphyxia. Resuscitation with adequate pulmonary ventilation, assuring a tidal exchange of from 300 to 400 c.c., should be the objective, and should be accomplished by means of positive pressure inflation with oxygen, and the available anesthesia apparatus. Positive pressure of 20 mm. of mercury is almost always required to inflate the lungs of an adult.

Anesthesia should be placed in the hands of trained specialists, who would promote teaching and stimulate discussions of anesthesia problems.

The maintenance of a clear airway is essential. Patients subjected to spinal anesthesia must be watched as closely as those under general anesthesia. Most deaths on the operating table during major thoracic surgical procedures are the result of obstruction and acute anoxia, and not of vagovagal reflexes. Every anesthetist who attempts the responsibility of anesthesia in thoracic surgery should be an expert bronchoscopist. MARY KARP, M.D.

Lenahan, N. E., and Elliott, D.: Ether Convulsions. Discussion and Presentation of a Case. *Current Res. Anesth.*, 1946, 25: 31.

The so-called "ether convulsions" are not really due to ether. Several factors must be present at the same time and in certain ratio or proportion to produce them. The strength of the stimulus required to initiate the convulsions will depend on the potency of the predisposing conditions. It has been shown that from 20 to 30 per cent of carbon dioxide will induce convulsions in the anesthetized human subject. Pyrexia increases the response of the patient to carbon dioxide.

The factors which may cause or predispose toward convulsions are:

- A. Those present before anesthesia
 1. Specific factors associated with the nervous system
 - (a) Individual susceptibility—youth, convulsive diathesis
 - (b) Cerebral effects of the disease—edema, vascular disease, specific organisms, or neurotoxins
 2. Nonspecific factors affecting cerebral irritability which result secondarily from disease or toxemia

- (a) Calcium deficiency, ketosis, alkalosis, thymic syndrome, fever, renal insufficiency, imbalance of the autonomic nervous system, and abnormal metabolic states

B. Those related to anesthesia or surgery

1. Impurities in the anesthetic agent
2. Modification of the internal and/or external environment by drug action, technical method, or surgical procedures

- (a) Anoxia, faulty carbohydrate metabolism, temporary renal insufficiency, acid-base imbalance (metabolic and respiratory acidosis), abnormal distribution of body water and osmotically active ions, defective heat regulation, high environmental temperature, and reflexes from operative trauma

One case was reported in detail, that of a 3 year old child operated on for surgical repair of extrophy of the bladder, who developed generalized twitchings after 2 hours and 15 minutes of open ether anesthesia. She was treated with oxygen and 5 per cent glucose in normal saline solution given intravenously. She recovered uneventfully without any evidence of personality changes.

For the treatment of convulsions it was suggested that the anesthetic be withdrawn at once, and that oxygen be given. Calcium glucose should be administered intravenously. The heart should be supported by a stimulant and barbiturates should be given to overcome the convulsive seizure.

MARY KARR, M.D.

Gill, R. G.: Curare; Misconceptions Regarding the Discovery and Development of the Present Form of the Drug. *Anesthesiology*, 1946, 7: 14.

A brief historical resumé of curare included the following facts:

1. It was known and used by the Indians of South America as an arrow poison during and since pre-Columbian times.

2. Civilized nations learned of it as early as 1595 when Sir Walter Raleigh, after his voyage to the Orinoco, told of its use by the natives.

3. Watterson and Brodie in 1815 demonstrated that asphyxia was the cause of death in curare poisoning.

4. A few years later Claude Bernard, the French physiologist, discovered the physiological action of curare upon the neuromuscular junction.

The author points out that there are certain misconceptions constantly appearing in the literature which are related both to the background of curare and also to its current employments. An outstanding example of misinformation which appears in various publications is that curare is an unpredictable drug and that the "dosage is unreliable." The Federally accepted ampule curare, however, is unvarying, reliable, and predictable.

All types of curare, both primitive and evolved, have contained a complex of known botanical in-

redients, and are not from any single species, genus, or even family of plants. It is not made from the bark of the strychnos group (loganiaceae family) alone, nor does the chondrodendron species (Menispermaceae family) deserve a similar ethnobotanical "monopoly."

There are also errors relating to the geographical distribution of curare. For instance, a popular pharmaceutical index states: "Habit, Orinoco, South America, the arrow-poison of the Orinoco Indians." Factually, the Orinoco basin of South America is a far less productive source than other and larger regions of Amazonian drainage throughout northern and western South America.

A major misconception appearing in various well known publications is that the varieties of curare are designated by the kind of containers in which they reach commerce. The type of native container (dried gourd, bamboo tube, or small clay pot or jar) is in no way an indication of the kind of curare. It depends entirely upon which first comes to the hand of the Indian maker, and may vary from day to day.

Still other categories of scientific error and misconception continue to appear in the literature. These relate especially to the pharmacodynamics of the substance and its physiological actions. This is apparently the classical beginning of any new drug, and, fortunately, many of these errors seem about to disappear.

This interesting and informative article closes with a plea that curare be administered by medical anesthetists only. The administration of the drug and the handling of the curarized patient is as responsible "an incursion into that field legally defined as the 'practice of medicine' as is the administration of any anesthetic agent per se."

EDITH EASON, M.D.

Harbroun, P., Beckert, F. E., and Hathaway, H. R.: Curare and Nitrous Oxide Anesthesia for Lengthy Operations. *Anesthesiology*, 1946, 7: 24

Curare and nitrous oxide have been used for the past 7 months at the University of California for a number of lengthy surgical procedures.

Following ample medication, nitrous oxide and oxygen were administered until the patients were in first plane anesthesia. After a pharyngeal airway had been inserted, the anesthetist's ability to inflate the patient's lungs was tested. Curare (from 150 to 200 mgm.) was given intravenously, this dosage usually producing apnea. When muscular relaxation occurred an orotracheal tube with an inflatable cuff was inserted under direct vision. The nitrous oxide mixture was then administered through this tube by means of the carbon dioxide absorption technique, the patient being maintained in first plane anesthesia. Further amounts of curare were given as needed to produce the relaxation required at various stages of the operations. The patients reacted to lack of oxygen by muscular rigidity, or to excess carbon dioxide by increased respiratory efforts even though large doses of curare were used. The pa-

tient's lungs were adequately ventilated at all times, either by the patient himself or the anesthetist.

During the first of the series dilatation of the intestine was an embarrassing complication in a few instances. Morphine was administered for this condition and satisfactory constriction resulted. A comparison with patients who received other types of anesthesia was made. The curare group had fewer postoperative complications. Most of the patients had marked muscular weakness which persisted for several hours. This necessitated careful postoperative nursing with frequent change of position.

It was believed that this combination provided adequate relaxation for surgery, and at the same time did not endanger the patient's well being by long periods of deep anesthesia. The usual anesthetic techniques, when prolonged over a period of 4 hours or more, often produce signs of circulatory disturbance.

EDITH EASON, M.D.

Mayer, E. C., Jr., and Neff, W.: Further Experiences with Endotracheal Ether-Air for Intrathoracic Surgery. *Anesthesiology*, 1946, 7: 32.

A method is presented of using ether-air anesthesia with a simple apparatus for intrathoracic operations. The original intention was to provide a means whereby anesthesia and ventilation could be maintained while the chest was held open for long periods of time under emergency, and when the "to-and-fro" carbon dioxide technique apparatus was not available. Because of the satisfactory results obtained the method was continued in civilian work. This report includes 50 intrathoracic operations which were performed under this anesthesia technique.

Induction is usually accomplished with pentothal or nitrous oxide and ether. An oroendotracheal tube

is inserted under direct vision. This is connected directly to the Stanford vaporizer. When the thorax is open, ventilation of the lungs is accomplished by rhythmically and intermittently inflating them by the valve and bellows method. Respirations are controlled by inflating the patient's lungs from 15 to 20 times per minute at a pressure of 10 mm. of mercury. If positive pressure is not required when a fixed mediastinum prevents paradoxical respiration, and in pericardiectomies in which the approach is made directly into the anterior mediastinum, an improvised exhalation valve is inserted between the endotracheal tube and the vaporizer in order to reduce the dead space in the apparatus to a minimum.

Maintenance is usually conducted in midsecond plane anesthesia. There is a discussion of the management and maintenance of anesthesia, and the conclusion of anesthesia, with special emphasis on re-establishment of spontaneous respiration. Careful tracheobronchial suction is performed before removal of the endotracheal tube.

Supportive treatment includes replacements and drug therapy. Oxygen is given continuously after operation for from 24 to 48 hours.

Accidents included the mistaken connection of the Levine tube to an oxygen catheter and aspiration of vomitus.

A clinical study of the 50 cases is given in a detailed chart. The youngest patient operated on was 8 months old, and the oldest 75 years. The shortest operation took 50 minutes and the longest 7 hours and 50 minutes.

This method is presented as a possible technique of choice for intrathoracic operations even though the more elaborate equipment is available.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Finland, M., Ritvo, M., Davidson, C. S., and Levenson, S. M.: Roentgenological Findings in the Lungs of Victims of the Coconut Grove Disaster. *Am. J. Roentg.*, 1946, 55: 1.

A correlation of the roentgen findings with the clinical manifestations in 87 cases is reported from the Boston City Hospital, Boston, Mass. There were roentgenographic changes in 71 of these cases; 51 per cent had comparable clinical and roentgenographic findings; 33 per cent had more extensive, and 5 per cent much more extensive, clinical than roentgen findings; while only 11 per cent had more extensive roentgen than clinical findings. No correlation was noted between the roentgenographic changes and the extent of the surface burns. There were 15 deaths. Only a few of the patients were roentgenographed before the first 36 hours.

The authors state that the roentgen findings in their group are very similar to those reported by Schatzki in the *Annals of Surgery*, (1943, 117: 841). (These findings were made at the Massachusetts General Hospital, Boston, Massachusetts.)

Most, if not all, of the visible roentgen findings are believed to be due to interference with aeration from partial or complete obstruction of the bronchi, especially the smaller ones. Atelectasis, patchy or diffuse, was present in all but 1 of the positive roentgenograms. In only 1 instance was a complete massive atelectasis observed. Mottling, coarse or fine, was the next most common finding. Early and in the more severe cases a diffuse military type of mottling of both lung fields was observed. In other cases mottling was limited to one or two lobes. Emphysema, patchy and diffuse, also occurred frequently. Roentgenograms made during expiration were advantageous in bringing out the findings.

Increased hilar markings were present in 62 of the 70 roentgenographic positive cases. In 50 per cent of these cases the findings were unilateral. Only 5 cases showed consolidation and this was mostly patchy in distribution. Pulmonary edema was not observed in any of the roentgenograms, nor was extensive pulmonary edema found at autopsy.

In general, the more extensive roentgen findings had cleared before the end of the first week. However, small areas of atelectasis and patches of emphysema with increase in the hilar shadows persisted longer in some of the cases. Follow up studies from 6 months to 2 years later on the patients who had moderate or extensive roentgenographic changes showed no abnormalities. R. B. LEWIS, M.D.

Hodes, P. J., and Keefer, C. P.: Hookworm Disease. *Am. J. Roentg.*, 1945, 54: 728.

The authors report on 125 cases of proved ankylostomiasis in American troops cared for at an

Army General Hospital in the Province of Assam, in India, during a period of over 2 years, 60 per cent of whom showed roentgen abnormalities of the small intestine. Both ankylostoma duodenale and necator americanus are found in Assam where the native population shows a high rate of infestation. Approximately 80 per cent of the troops concerned came from areas in the United States in which hookworm is not a public health hazard, and all men were in excellent health on arrival in the China-Burma-India theater. In 80 per cent of the cases the disease was believed to have been of less than 3 months duration, and in the remainder, not over 6 to 8 months. Sixty-five per cent of the patients had clinical evidence of "hookworm disease"; the remaining patients came to the hospital as battle casualties, or were suffering from other diseases, and the positive stools were an incidental finding.

The clinical histories were frequently classic. Often the patient dated the onset of "ground itch" to a time when he had been lying in a fox hole for several hours, and localized it to that part of the body exposed to mud or water. The pruritus and dermatitis lasted from 4 to 7 days, and within a period of from 1 to 2 weeks after its onset a dry cough began, which was followed in turn by gastrointestinal symptoms. The latter appeared from 6 to 25 weeks after exposure of the skin to the larva-infested soil, and were often ushered in by an acute attack of nausea, vomiting, abdominal pain, and diarrhea. Diffuse epigastric pain of a burning or cramping character, often made worse by food, was the outstanding complaint, and half the cases had diffuse upper abdominal tenderness. In contrast to the anemia described in chronic hookworm disease, the red blood count and hemoglobin estimates were normal in all but 3 cases. The white cell count averaged 15,000, but varied from below 10,000 to over 40,000; eosinophilia was usually marked, ranging from below 10 per cent up to 80 per cent. Patients showed no evidence of frank malnutrition; plasma proteins were not ascertained.

The patients were given, orally, 5 oz. of barium in 5 oz. of distilled water, and were examined fluoroscopically at once and every 30 to 45 minutes thereafter for about 3 hours, films being obtained at 30 to 60 minute intervals. Similar studies had been made on 10 healthy members of the Command on arrival in the war theater and again 16 months later, and all appeared normal.

The roentgen changes noted in the patients with hookworm were, in general, comparable in degree to the clinical severity of the disease, and consisted in tenderness of the upper small bowel on direct palpation of loops, luminal narrowing, rugal fold distortion manifested by thickening and constantly shifting irregularity of valvulae conniventes with widening of the valleys between them, accentuated peristalsis.

and occasional localized fleeting dilatation of various segments. The proximal jejunum was the region most frequently and markedly affected, although in the more severe cases the changes spread into third and fourth portions of the duodenum and into the distal jejunum; and in some instances there were even minor abnormalities of the proximal ileum, a distribution which tallies well with known sites of hookworm infestation.

About 20 per cent of the patients were examined in from 2 weeks to 6 months after treatment, and most of them showed improvement in or disappearance of the abnormal roentgen findings, but in some the findings remained little changed long after the patient appeared clinically well. The abnormality which persisted longest was the labile distortion of the rugal fold pattern.

The authors feel some hesitancy in ascribing an irregular fold distortion, able to undergo lightning-like shifts in thickness, height and direction, to actual thickening of the wall of the intestine, and suggest that these changes may be due, at least in part, to a damaged intramural nervous system, a possibility which would help to explain the long post-treatment persistence of labile fold distortion in some patients who had become clinically well.

LILIAN DONALDSON, M.D.

Graff, W. S., Scott, K. G., and Lawrence, J. H.: The Histological Effects of Radiophosphorus on Normal and Lymphomatous Mice. *Am. J. Roentg.*, 1946, 55: 44.

Two series of experiments were performed by the authors. In the first, three-month and five-month mice of the "A" strain were made lymphomatous by the intravenous injection of 1.2×10^7 lymphoma cells. Thirteen days following the inoculation some of the lymphomatous mice received 195.3 microcuries (beta ray standard) of P^{32} intravenously. (The lethal dose for mice of this size is about 70 microcuries.) A second series was made lymphomatous in a similar fashion, but received P^{32} 7 days later in 4 doses of 54.5 microcuries each every 2 hours. Suitable controls were kept in both series. Blood studies included white and differential counts. Red cell and hemoglobin determinations were not done.

In both series the drop in the white count was greater in the leucemic animals than it was in the controls during the first 4 days. In the following 5 days the white count in series 1 approached a plateau, while in series 2 the drop continued. In the control animals the small lymphocyte was first most markedly affected. The mature granulocyte was relatively little affected. However, at the end of 14 days both the lymphocytes and granulocytes were diminished. Approximately the same results were observed in the lymphomatous series and the leucemic cells were also diminished for 9 days. P^{32} delays lymphomatous invasion of the liver, bone marrow, lymph nodes, and spleen.

An attempt was made with sublethal doses of P^{32} to obtain "cures" of lymphomatous mice. For these

experiments intraperitoneal suspensions of granulomatous cells were used. After demonstrable tumors were produced, varying amounts of P^{32} were given intraperitoneally over periods of from 9 to 16 days. Regressions were observed in 5 of 31 treated animals. The dosage was just sublethal. Further observations of these "cured" animals were not made because of a change in the activities of the laboratory in 1941.

The authors conclude by stating, "We must look for the control of this disease (leucemia) by some method other than irradiation." R. B. Lewis, M.D.

Evans, T. C., and Quimby, E. H.: Studies of the Effects of Radioactive Sodium and of Roentgen Rays on Normal and Leucemic Mice. *Am. J. Roentg.*, 1946, 55: 55.

It has been thought desirable in the administration of radioactive elements to use those substances which are preferentially absorbed by the tissue to be treated. For example, radioiodine for the thyroid, and radiophosphorus for bone, bone marrow, leucemic tissue, and any rapidly growing cells. The treatment of leucemia with radiophosphorus is still in the experimental stage. The results obtained have been about the same as those obtained by roentgen therapy.

It was thought that radiosodium, because of the generalized distribution in the body of sodium and the short half life (14.8 hours) of the radiosodium, might be advantageous in the treatment of leucemia. The effect should be due to the rather uniform irradiation of the entire body. Experiments were conducted to show the effect of radiosodium on normal and leucemic mice. A parallel series was done to show the effect of roentgen irradiation. In normal rats, doses of from 3,000 to 4,000 microcuries were fatal in 2 weeks. A temporary reduction in the leucocyte count was produced by a dose as low as 300 microcuries. With increase in the dosage the white blood count was lowered, the duration of the leucopenia was increased, and the survival time diminished. From 350 to 1,000 r. of roentgen rays given to normal rats, 70 per cent on the first day and 30 per cent the next, produced results similar to the radiosodium. From figures so obtained it was calculated that 10 microcuries per gram of body weight is equivalent to 100 r. in mice. In human beings it is estimated that the roentgen equivalent would be at least double.

Leucemic mice with enlarged lymph nodes (strain Ak) were treated with radiosodium (animals with counts below 30,000 were considered aleucemic). The enlarged nodes disappeared, at least temporarily, with doses so low as to barely affect the white count. Larger doses produced the effect more quickly.

Leucemic mice with adenopathy were treated with radiosodium. In general they showed more reduction in lymphocytes than did the control animals.

On the average, the difference in the elimination of radiosodium by the leucemic animals and by the

normal animals was found not to be statistically significant. Several of the leucemic animals were sacrificed at various intervals and various portions of their bodies analyzed for radioactivity. There was no considerable concentration of the radiosodium in any particular organ or tissue. R. B. Lewis, M.D.

Strand, S.: On Keloids and Their Treatment. *Acta radiol.*, Stockh., 1945, 26: 397.

A review of the recent literature on keloids and a study of the results of radium treatment in 117 cases is presented. The actual cause of keloid growth is still unknown, although individual, family, and racial predispositions are apparent. Tissue predisposition seems to be partly local and partly general and is somewhat limited in time. Keloid growths show no tendency to malignant degeneration, although in old scars with keloid nodes, cancer of the epidermis has been observed to develop without any evidence of causal connection between the cancer and the keloid. Multiple keloids may suggest multiple sarcomas, but the appearance of the keloid with its smooth, atrophic skin and characteristic branched spreading renders the diagnosis an easy matter.

Since the cause of keloids is unknown, preventive treatment cannot be given. If a keloid is removed surgically, a recurrence will practically always occur, and often will be larger than the original keloid. Radium treatment has proved to be more rapid and certain of producing a good result than roentgen treatment, and lends itself to a more accurate and limited application so that it has become the treatment of choice. Combined surgical and radiation therapy is rarely used, not only because the result is unsatisfactory, but also because radiation alone has given such good results. Where the keloid lies over a joint and impedes its function, a plastic operation followed by irradiation is indicated.

The technique used in this series of 117 cases covering a ten-year period employed a radium mold with a radium-skin distance of 0.7 cm. and a filter of 0.7-1.0 mm. platinum. Molds were adjusted to render about 560 r. in 24 hours, and treatment extended over a period of 3 to 4 days to give a total of about 1,410 to 2,060 r. An attempt has been made to adjust the treatment to the probable radiosensitivity of the individual keloid, the age of the patient, and of the keloid, its extension and elevation above the surrounding skin having been considered. Regression appears only after from 7 to 8 weeks, and continues during several months to a year. Repetition of treatment with a somewhat smaller dose has been carried out in 36 cases, and a third treatment has occasionally been given. In a few cases slight permanent radiation changes have appeared in the skin. The result of treatment has been estimated as follows:

Very satisfactory regression in 67 cases (57%); good regression in 38 cases (32%); some regression in 7 cases (6%); no regression in 1 case (1%); and unknown regression in 4 cases (4%).

The type of trauma causing the keloid did not seem to influence the sensitivity of the keloid to radium treatment. A study of the influence of the age of the keloid on the result of treatment indicated that all cases treated during the first 6 months responded favorably, and that during the first year no case showed a poor reaction to treatment. Later an increasing number of cases reacted less satisfactorily to treatment. A study of the influence of the patient's age on the response to treatment showed that below the age of 10, all patients reacted well, but in the age group of 10 to 20 years a few showed only some regression. The results for the group over 20 years seemed to be somewhat below the average. The influence of age of the patient on the result of treatment appeared to be of less importance than the age of the keloid. In no case has there been a recurrence of the keloid or a regression of the effect obtained by radium treatment.

JOHN L. LINDBQVIST, M.D.

Mustakallio, S.: The Possibilities of Roentgen Therapy in the Treatment of Cancer of the Breast (*Ueber die Möglichkeiten der Röntgentherapie bei der Behandlung des Brustkrebses*). *Acta radiol.*, Stockh., 1945, 26: 503.

This article seems to be an attempt to answer the contentions of Pack and Livingston, who in their book (*Treatment of Cancer and Allied Diseases*, New York: Paul B. Hoeber, 1940) have collected numerous statistics tending to show that roentgen treatment is of doubtful value as an adjunct to radical surgery in mammary carcinoma, for when all cases of operable breast cancer treated by radical amputation are considered, the 5 year cures amount to about 40 per cent, whether or not the operation be preceded or followed by roentgen irradiation.

The author does not attempt to confuse these figures; as a matter of fact in his material, including all patients undergoing radical amputation of the mammary gland for carcinoma combined with roentgen therapy, the figure for 5 year cures was 38 per cent. However, it is obvious that the operation of radical amputation of the breast is not only a mutilating procedure accompanied by psychic trauma; it causes the development of elephantiasis (temporary in 15 to 20 per cent, and permanent in 10 per cent of the patients) and the loss of earning capacity, and is of such tremendous scope that it is bound to weaken the patient generally, and the author maintains that this will have a bearing on the course of the disease itself.

He also maintains—and adduces authorities to support his contention—that there is a defense mechanism within the body which resists the growth and spread of the malignant process. For instance, of the 194 deaths within 5 years in the author's total material of 384 breast cancers in the years 1936 to 1945, almost all of them were due to distant metastases. In the cases of amputation the dissemination of the cancer cells, from which these distant metastases later developed, must have occurred at varying

periods prior to the operation itself and the cells must have lain dormant and unable to grow until some incident—perhaps the breast amputation—had lowered bodily resistance to the invading new growth. At least some sort of mechanism has been shown in the transplantations of tumor in the animal, in which relatively enormous numbers of cancer cells (450,000) must be introduced in order to start a growth, and there is other evidence, even in the author's material, that such a mechanism of resistance might exist, for instance, in the patients who developed a generalized carcinosis terminally. New metastasis would appear at times in the skin, as though the debilitating effects of the deep process would allow the previously dormant cell nests in the skin to start growing.

A further indication of the presence of some defense mechanism is seen in the results with roentgen therapy in the inoperable patients who were sent in for irradiation. In these the prognosis as regards life was not good; nevertheless, under the intense irradiation treatment as administered by the author, some of these 92 patients were still alive and free of symptoms from 3 to 5 years after initiation of the treatment. In the author's opinion this indicates that the resistance forces of the body toward the metastases at a distance, which must surely have been present previously, were increased by roentgen therapy to such an extent that the patients were free from signs of activity of their disease during this time.

However, the strongest case against radical amputation of the breast as the sole operation of choice when the tumor is still operable seems to be the 23 relatively early cases in the author's material in which a local excision was all that was done before the patient was turned over to the author for irradiation treatment. A large table, covering several pages, shows the particulars of each one of the 13 patients who were under treatment and observation for at least 3 years. It shows that the dimensions of the tumors varied from fist size to sizes so small that the new growth was palpable with the fingers; it shows that 8 of the 13 women had received intensive preoperative roentgen treatment, and that in some of these the tumor had become much reduced in size; in 1 case all living cancer cells had disappeared. Of course, the author does not contend that in a certain percentage of cases, even with simple extirpation of the tumor combined with roentgen treatment, metastases will not develop; however, it has appeared to him thus far that the percentage of metastases is at least not any greater than in the cases treated by radical operation.

Therefore, in the very early cases of breast cancer which are treated by local extirpation of the tumor combined with preoperative irradiation good results can be obtained, while, on the other hand, a radical operation cannot prevent the development of metastases. In 20 per cent of the author's material, in which the cause of death was known to the author, metastasis could not be determined when irradiation

treatments were started. Ninety per cent of the patients in whom such metastases could be determined died of metastasis at a distance despite radical operation. The author therefore believes that since radical amputation of the breast is an already pretty much perfected method, of which the possibilities have been fairly well exhausted, the profession should turn cautiously toward a more conservative type of therapy consisting of tumor extirpation combined with intense irradiation treatments.

JOHN W. BRENNAN, M.D.

MISCELLANEOUS

Thoren, S.: Electroendothermy as an Adjuvant to Radiotherapy in Uterine Cancer. *Acta radiol.*, Stockholm, 1945, 26: 249.

From July, 1928 to August, 1938, inclusive, electro-surgery (electroendothermy) was used in the Radium Hemmet of Stockholm as an adjunct to irradiation in the treatment of uterine cancer in 85 cases. Of these, 82 were carcinoma of the cervix and 3 carcinoma of the corpus uteri. Fifty-five patients with carcinoma of the cervix underwent electro-surgery in the last 20 months of this period. Electroendothermy was used in 8 cases of cervical carcinoma for hemostasis only. Thirteen patients had extensive involvement of the parametrium, and of the pelvic and abdominal walls when first seen and were considered hopeless. The remaining 61 patients with carcinoma of the cervix uteri were treated with radium and x-rays according to the Stockholm method, followed by electro-surgery in 55 cases within the succeeding 2 years and in 6 cases after more than 2 years.

The primary carcinoma was histologically identified in all cases, and the metastases, recurrences, and remnant tumors in 37 cases. The results were as shown in Table I.

The main indications for electro-surgery were: (A) in cancer of the corpus: vaginal metastases in all 3 cases; (B) in cancer of the cervix: (1) incomplete disappearance of the tumor, (2) local recurrence of the tumor, and (3) radium necrosis and cases in which the preoperative distinction between tumor and radium necrosis could not be made. Other indications were pelvic metastases, cases which ordinarily would have been subjected to hysterectomy, inoperable cases, and poor operative risks.

The preoperative diagnoses roughly grouped are shown in Table II.

Eighteen case histories of carcinoma of the cervix and 3 of carcinoma of the corpus are presented; all of these cases were treated by irradiation and electro-surgery. Two techniques were used:

1. Bipolar endothermy with two large inactive electrodes applied to the patient's back and arm, and a small plate or ball shaped active electrode pressed into the tissue to be coagulated. Spraying of the field with cold water is necessary in order to prevent loss of tissue conductivity due to superficial coagulation.

TABLE I.—SIXTY-ONE CASES OF CANCER OF THE COLLUM TREATED WITH EE FOLLOWING IRRADIATION

Type of case	Number of patients	Alive without evidence of the disease 4 years after EE operation	Died of cancer		Died of intercurrent disease. No cancer at autopsy
			Local recurrence	Metastases but no cancer in the treated area	
Superficial focus	35	13	14	5	3
Deep focus	7	0	7	0	0
Deep focus and additional involvement of parametrium	11	3	8	0	0
Metastases in the lower vagina	8	1	4	3	0

TABLE II.—PREOPERATIVE DIAGNOSIS

Clinical interpretation of the cases previous to EE	No. of patients	Alive without evidence of the disease more than 4 years after EE operation	Died of cancer		Died of intercurrent disease. No cancer at autopsy
			Local recurrence	Metastases, no cancer in the treated area	
Interpreted as cancer	48	11	28	7	1
Uncertain whether cancer or radium necrosis	10	5	4	0	1
Interpreted as radium necrosis	3	1	2	0	2

2. Fulguration: with this method the tissue around the electrode is charred and becomes non-conductive very rapidly. This prevents deep coagulation, which is a safety factor. The coagulated tissue is removed by curettage, the fulguration is started anew, and the process is repeated until the desired depth is reached

The complications due to these procedures were: rectovaginal fistulas in 2 cases, and peritonitis due to rupture of a pyosalpinx in 1 case.

In conclusion, the author states that electro-surgery is a valuable adjunct to the irradiation therapy of uterine cancer.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Clark, W. E. LeG.: *The Contribution of Anatomy to the War. Brit. M. J.*, 1946, 1: 39.

This report is a short survey of some of the contributions of anatomy to war problems. In the Department of Anatomy at Oxford University alone, apart from the articles of which publication was not prevented by security regulations, the number of confidential scientific reports and memoranda prepared during the recent war by the staff amounted to 104.

In the field of traumatic surgery a great deal of work on fundamental processes of tissue repair was carried out which has been of value in research into problems of nerve regeneration, of burns and their treatment, of skin grafting, of vascular supply in the muscles, and of muscle regeneration. Much of the results of this work has been published.

Studies were made on the effects of high velocity missiles of small size, and of blast. A standardized casualty rate was calculated indirectly for different types of weapons by reference to (1) the relative vulnerability of different parts of the body, (2) the striking velocity of missiles necessary to produce incapacitating wounds, (3) the mean projected vulnerable area of the body, and (4) data regarding the fragmentation of explosive projectiles and the velocity of fragments at varying distances.

The purpose of another type of research could be defined as "fitting the machine to the man." This work required an extensive anthropometric survey of Service personnel in order to get adequate information on body measurements and their range of variation, as well as the amplitude of movement of those joints of the body which are specifically used in the operation of machines of different types. In some cases an assessment of the force which can be exerted by the operator at various phases of movement was required. From the data of these investigations a machine could be designed that would fit the man and enable him to work efficiently.

It is suggested that the type of research organizations developed during the war should be continued during peace for the solution of peacetime problems.

JOHN L. LINQVIST, M.D.

Wilson, T. E.: Plasma Protein Estimations in Battle Casualties. *Med. J. Australia*, 1946, 1: 153.

A group of 13 severe battle casualties are reported. In these cases serial plasma protein determinations were made by means of the falling drop method. The results were tabulated in some detail and hypoproteinemia was demonstrated. The lowest value reported was 4.45 gm. per cent.

The value of this test in discovering cases of concealed hemorrhage and as a guide in the treat-

ment of severe trauma is discussed. Its use in other conditions such as burns, intestinal obstruction, and peritonitis is mentioned.

The replacement of blood volume, fluids, and proteins is discussed. THOMAS C. DOUGLASS, M.D.

Knisely, M. H., Elliot, T. S., and Bloch, E. H.: Sludged Blood in Traumatic Shock. Microscopic Observations of the Precipitation and Agglutination of Blood Flowing through Vessels in Crushed Tissues. *Arch. Surg.*, 1945, 51: 220.

The authors state that this article is the first of a series describing some of their studies of the pathological circulatory physiology of animals and men, preceding and during traumatic shock. They had two purposes in writing this article: (1) to introduce this series of studies on traumatic shock and relate them to other work from their laboratories, and (2) to describe the initiation of some microscopically visible changes in the physical consistency of the circulating blood which are caused by mechanical injuries to the tissues (cutting or crushing injuries), but which have not yet been found to be caused by hemorrhage alone.

In addition to the studies of the changes in the blood, vessel walls, and circulation, preceding and during traumatic shock, which have been introduced by this article, the authors are carrying out a larger series of studies of normal and pathological circulatory physiology. There is the microscopic study of:

1. The circulation in a number of tissues and organs of laboratory animals under the most nearly normal conditions which have been attained experimentally.
2. The mechanical consistency of the circulating blood.
3. The circulatory physiology of normal macacus rhesus monkeys and of monkeys infected with plasmodium knowlesi malaria.
4. The reactions of various parts of the vascular system during and following hemorrhage initiated with a minimum amount of mechanical trauma to animals.
5. The reactions of the blood and vascular system, and the changes in the circulation following mechanical trauma made with a minimum amount of hemorrhage from animals.

The methods used for studying the blood and small vessels with microscopes are described in detail. The discussion of the various controls necessary in this kind of study is presented at length, and the description of microscopic experiments with mechanical trauma on the omentum of a monkey is given, as well as descriptions of experimental crushing of mouse striated muscle.

For distribution of emphasis the authors present a summary and conclusions divided into sections

dealing (1) with controls, (2) with the methods, and (3) with the results of crushing injuries.

They note that after a crushing injury to monkey omentum, smooth muscle of mouse intestine, or striated muscle of a mouse, three zones may be distinguished: (a) a thrombosed zone, (b) a partially crushed or sludging zone, and (c) a zone which is injured so little that the blood flowing through it undergoes no detectable change.

In studying the possible initiating factors of traumatic shock, the following observations were made in these tissues: crushing plus flow through a vessel in the crushed area yields a stream of sludge into the general circulation; crushing plus thrombosis of a crushed vessel yields no sludge to the venous system, and flow without crush yields no sludge.

Thus, after trauma, local crush plus flow through a vessel in the crushed area are both necessary and, together, sufficient to yield a flow of sludged blood into the general circulation. After crush, precipitates can form around or between the moving blood cells in less than a second, while the blood is moving less than a millimeter.

It seems reasonable to suspect that the sludge initiators substances might be related to the substance capable of initiating blood clotting. If this is true, then many tissues and organs of vertebrates should release such substances when they are injured. At no time can sludged blood pass into the venous system faster than the flow through the crushed tissue.

For a time after the crush, the rate at which sludge is poured into the venous system can be as fast as the rate of flow through an open vessel in the crushed area. Retraumatization of an area can reinstate sludge formation in blood flowing through the area. This sludge can be formed in an area from which or into which there is no hemorrhage and but little loss of plasma through injured vessel walls. This sludge is also formed in the partially crushed regions of areas injured severely enough to cause local transudation of plasma, diapedesis of the red cells, and hemorrhages through the walls of the injured local vessels.

When first formed, some of the masses have sufficient internal rigidity to bulge the walls of the vessel through which they are being forced: if not changed, such masses would resist passage through the capillaries.

When first formed, the outer surface of the precipitated material is sticky to itself; hence, if not changed, such masses must, whenever they touch each other, tend to stick together and form larger masses.

The outer surface of the red cell masses formed in the blood flowing through crushed tissues is not visibly different in appearance or in behavior from the coated red cell masses formed in monkeys with plasmodium knowlesi malaria.

Hence, the precipitated coating with red cells which is formed in the blood flowing through crushed tissues may be ingestible by phagocytes of the

spleen, bone marrow, and liver. In monkeys with malaria, this mechanism destroys blood rapidly. During periods when the rates of production of sludge are faster than the rates of removal or resolution of the sludge, sludged blood should accumulate throughout the vascular system. If one injury or a group or a series of injuries were large enough and the flow through their sludging zones fast enough, all the circulating blood should change to a thick, mucklike sludge.

HERBERT F. THURSTON, M.D.

Tagnon, H. J., Levenson, S. M., Davidson, C. S., and Taylor, F. H. L.: The Occurrence of Fibrinolysis in Shock, with Observations on the Prothrombin Time and the Plasma Fibrinogen during Hemorrhagic Shock. *Am. J. M. Sci.*, 1946, 211: 88.

Fibrinolysis has been observed previously in patients who died in peripheral vascular failure. This was noted especially in the Soviet Union by Yudin and his colleagues following the use of cadaveric blood for transfusion.

Studies of fibrinolytic activity were made in 22 patients in a state of peripheral vascular failure. The results are shown in the table below.

Three of the patients with thermal burns were treated effectively for shock. With recovery from that state the fibrinolysis disappeared.

Observations were also made on dogs with shock experimentally induced by bleeding. In 13 animals one large bleeding was used to produce hypotension of from 40 to 50 mm. of mercury and this level was maintained by repeated small bleedings. No anticoagulant was used. In a series of 6 dogs, death by exsanguination was produced in from 5 to 18 minutes. Blood samples in the latter series were taken every 1 or 2 minutes. Determinations of the prothrombin time and the plasma fibrinogen level were made in some animals as well as observations on fibrinolysis.

Of the 13 dogs in sustained shock (first series) 5 showed fibrinolysis. In no instance did the latter phenomenon occur during the first 2 hours following the onset of shock. Simultaneous samples of venous and arterial blood were obtained from 1 animal. Fibrinolysis appeared sooner in the venous sample. All but 1 of the dogs that failed to exhibit fibrinolysis died during the fourth hour of shock. Measurements of the prothrombin time were made simult-

TABLE I.—FIBRINOLYSIS IN SHOCK (IN MAN)

	No. of Cases	Fibrinolysis
Burns		
Shock	3	3
No shock	3	0
Hemorrhagic shock	4	4
Traumatic injury		
Shock	1	0
No shock	4	0
"Medical shock"	7	1

taneously with the fibrinolysis observations on 8 animals. All of the dogs that survived over 2 hours showed a progressive diminution of the prothrombin in the blood, although 4 of them had demonstrated no fibrinolysis. The plasma fibrinogen level was measured in 5 of these animals and was found to fall along with the prothrombin.

Of the series of 6 dogs that were bled continuously, 3 showed terminal fibrinolysis but there was no significant change in the prothrombin and fibrinogen levels.

The authors attribute the phenomenon of fibrinolysis in shock to anoxemia. It is further suggested that this effect may be a manifestation of the presence of a circulating proteolytic enzyme from cellular elements of damaged tissue. The probability of the latter hypothesis is consistent with the finding in 1 animal that fibrinolytic activity was present in the venous blood some time before it appeared in the arterial blood.

An explanation of the fall in prothrombin and fibrinogen is not offered. However, it is suggested that the usefulness and indications of blood and plasma substitutes devoid of prothrombin and fibrinogen should be reconsidered if shock in human beings results in the reduction of the level of these substances in the blood.

THEODORE B. MASSELL, M.D.

Page, I. H.: Vascular Mechanisms of Terminal Shock. *Cleveland Clin. Q.*, 1946, 13: 1.

In terminal shock the survival of the shocked patient depends on the survival of the vital tissues, which in turn depends on the volume and rate of blood flow in the tissues. Observation of a patient with acute arsenic poisoning and extreme hypotension led to the belief that the level of arterial pressure was not the major determinant of tissue perfusion. In previously reported experimental work the author had observed constriction of the main visceral vessels and small peripheral vessels in the late stages of experimental shock. Vasoconstriction was attributed to the presence of an ultrafilterable substance in the plasma from the sites of tissue injury. With continued shock the vessels become refractory to chemical stimulation, and the terminal stage is heralded by cardiac and vascular dilatation.

On the basis of his experimental observations and confirmatory data from other sources, the author advocates intra-arterial transfusion for the treatment of late shock. An 18 gauge needle is inserted into the radial or femoral artery with the point toward the heart and blood is administered freely from a reservoir set at 50 mm. of mercury. When equilibrium is reached at this pressure so that the inflow ceases, the positive pressure is increased to 70 mm. of mercury, and so on, by increments, until a final equilibrium of arterial and reservoir pressure is reached at approximately 100 mm. of mercury. This point should be reached in a few minutes.

If it is believed that the vascular refractoriness appeared because of a long period of deep shock, it

sometimes seems desirable to give a small amount (200 mgm.) of 2-amino heptane into the infusion tubing just as the blood starts to flow in. The drug is used because it tends to constrict the heart and, as has been shown, cardiac dilatation is a serious danger in this stage of shock. The drug has no use apart from the coincident infusion of blood or plasma, and repeated doses are increasingly ineffective. It has not been shown to have value in the treatment of terminal shock either alone or in conjunction with intravenous transfusion.

The intra-arterial infusion method has several advantages. These seem to be: (1) the delivery of blood into the aorta perfuses the coronary vessels, and thereby relieves myocardial ischemia, and since myocardial ischemia probably underlies the cardiac dilatation and insufficiency, the heart is rapidly placed in a state in which it can pump the infused blood to other areas; (2) when, before the infusion, the patient may have been apneic, at its start he will take a deep breath, as if the arterial filling had rapidly extended to the vital medullary centers; (3) in contrast to intravenous transfusion, the blood pressure is rapidly restored, and the volume of blood infused is determined, not by time consuming analysis or by guess, but by the actual capacity of the vascular tree; and (4) a subsidiary advantage lies in the fact that latent bleeding, from the spleen, liver, or kidney, which causes arterial pressure to fall off rapidly, is detectable within minutes rather than hours.

THEODORE B. MASSELL, M.D.

Rosenthal, S. M., and Tabor, H.: Electrolyte Changes and Chemotherapy in Experimental Burn, Traumatic Shock, and Hemorrhage. *Arch. Surg.*, 1945, 51: 244.

Simplified and standardized methods of producing shock in laboratory animals have been utilized to effect shock by burn, trauma, and hemorrhage in large numbers of mice. Traumatic shock was produced by the application of rubber band tourniquets to the hind legs. Two hours later an increase of fluid in the injured part, equivalent to 3 per cent of the body weight, was demonstrated. There was an increase in the local quantity of sodium above that contained in the edema fluid, equivalent to the entire amount of sodium contained in the circulating blood or to one-fourth of the sodium in the extracellular fluid of the body, and a practically equivalent decrease in the local potassium: this suggested an interchange of the ions. Studies of the urinary excretion by animals which survived shock through the administration of isotonic sodium chloride solution showed a marked retention of the sodium during the first 48 hours, equivalent in terms of the isotonic solution to 20 per cent of the animal's body weight. In the same period the potassium excretion was over that of the control animals by more than twice the amount of potassium calculated to have been liberated from the traumatized area, which indicated some release of potassium from nontraumatized areas. That the potassium might be toxic was indi-

cated by the large amounts released. This hypothesis was supported by experiments in which potassium was administered to shocked and normal animals.

The experiments indicate that in shock there is dehydration of the sodium-containing extracellular fluid, the major portion of which must occur in the tissues. The tissue deficit must be corrected before a normal plasma volume can be maintained; and this requires the administration of large quantities of isotonic sodium solution. From the therapeutic standpoint, it is significant that after a fatal degree of burn, trauma, or hemorrhage the majority of animals survived if given an amount of isotonic solution of sodium salt equivalent to from 10 to 15 per cent of their body weights. Since all sodium salts tested gave the same result and other cations gave negative results, it is apparent that the beneficial effects depend on the sodium ion. In burn and traumatic shock the use of protein-free ultrafiltrate of serum indicated that the beneficial effect of serum was attributable to its electrolyte content. In hemorrhagic shock, however, whole blood or erythrocytes in isotonic sodium chloride gave better results than plasma or saline solution alone.

The authors emphasize the significance of fluid disturbances and specific electrolyte changes in the acute shock following burns, trauma, and hemorrhage. They advocate the administration of quantities of isotonic solutions of sodium salts equivalent to at least 10 per cent of the body weight during the first 24 hours and point out that such therapy is more important to survival than the administration of plasma proteins. The fact that such therapy may be given orally (one part of lactate solution to two of chloride for a palatable mixture) is of great practical importance. B. F. LOUNSBURY, M.D.

Crossman, L. W., and Allen, F. M.: Shock and Refrigeration. *J. Am. M. Ass.*, 1946, 130: 185.

The demonstration of the inhibition of shock by reduced temperature was the first break in the universal tradition of warming shocked patients or their injured parts. Both clinical and experimental observations now leave no doubt that the difference between high and low environmental or bodily temperatures can amount to the difference between life and death in shock.

The more radical refrigeration which can be applied to local regions has correspondingly powerful effects. It prevents pain and primary shock and thus can serve for operative anesthesia. Also, by temporarily arresting all local metabolism, secondary shock and all local reactions to injury are inhibited. Besides the reduction of the physical factor of exudation, there is halting of production and great diminution of absorption of all kinds of toxins, so that hypothermia is the only known treatment which can affect the toxic factor in shock. There is agreement in recent literature that these effects are sufficient to save life in suitable cases. In addition, the reduced temperature can augment the benefits and

remedy the defects of the pressure treatment. Alone or combined with pressure, the cooling may range from near freezing in a crisis to the moderate degree obtainable by the wetting of thin dressings with water or alcohol, or exposure to cool air or a fan current. There is no excuse for elevation of the temperature in any shock treatment, and the need for cooling is increased by hot weather or a febrile complication.

The first clinical use for operative anesthesia was described in 1937, but it did not receive a large scale trial until 1941. The reduction of mortality in poor risk amputation cases by the avoidance of shock and various complications has become familiar through many independent reports. A few misapprehensions may be corrected by the reminder that the prevention of hypotension by special measures during spinal or other anesthesia has no influence on secondary shock, and that a shockless thigh amputation is impossible except under refrigeration. The ability of patients to enjoy full meals immediately before and after refrigeration operations is a small illustration of the difference from other methods. The exceptionally low mortality statistics of a few operators are prima facie proof that their class of patients were strong enough to withstand shock, and if they find reasons for preferring other anesthetics under these conditions, at least the saving of many formerly "inoperable" cases by refrigeration is now established by sufficient testimony.

Many forms of trauma can be benefited by the unique power of cold to control simultaneously pain, shock, exudation, infection, necrosis, and the formation and absorption of toxins. Refrigeration is especially important in the treatment of burns and military surgery in general.

A form of benefit which no one has questioned is the checking of intoxication in infected gangrene. When operation must be deferred because of a moribund condition, refusal of consent, or other causes, the simple packing of such an arteriosclerotic limb in ice often transforms the condition dramatically within 1 or 2 days.

Closely related to this is the control of dangerous infections in limbs without arteriosclerosis. There is evidence that the chilling extends deeply enough to produce considerable effects on bacterial activity and toxic absorption, even without a tourniquet. The latter should be used in cases of expected amputation but not otherwise, and it should remain in place until after the amputation. The ice pack should extend all the way to the axilla or groin, to control invisible extensions of infection above the tourniquet. With or without a tourniquet, the purpose is usually a temporary arrest of an overwhelming invasion, affording an interval for building up resistance or for serum or other treatment.

Embolism of the limb arteries has been treated with refrigeration only at a late stage in order to avert impending gangrene when weakness, or cardiac or other complications contraindicated immediate operation. Such a respite for as long as several

weeks has sometimes been followed by successful amputation. There is evidence that cooling is equally effective in early embolism. The use in fresh embolism is closely paralleled by the experiences with trauma, often including thrombosis. The usual purpose is the immediate control of pain and shock and the prevention of infection and necrosis for a long enough time to permit of other needed treatments and recovery.

Amputated parts, on the other hand, can be preserved, as has long been known, in an ice box. Examples of severed fingers comparable to the severed legs of experimental animals have been shown. Preservation of such parts with refrigeration has become routine in England.

In the treatment of arterial spasm, refrigeration is rewarded with much success. Nerve blocking with procaine does not always release the supposed reflex. Since refrigeration anesthetizes both nerves and protoplasm, it should theoretically release arterial spasm even when procaine fails. Evidence of this is the noticeably full blood flow in stumps after ordinary amputations under refrigeration.

The fact that the necrosis following severe freezing is due to secondary thrombosis rather than a direct killing effect of cold is the basis of a new treatment in which the administration of heparin for 3 to 4 days brings about healing instead of sloughing.

The unique simultaneous inhibition of pain, shock, exudation, infection, necrosis, and intoxication recommends refrigeration as an ideal treatment for burns; it can also be combined with other treatments as desired. Plunging the involved part into cold water or applying ice not only gives the quickest emergency relief of pain and inflammation but also reacts most favorably on the later course.

STEPHEN A. ZIEMAN, M.D.

Freeman, S., Rhoads, P. S., and Yeager, L. B.: Toxic Manifestations Associated with Ertron Ingestion. *J. Am. M. Ass.*, 1946, 130: 197.

In 1 adult patient receiving doses of ertron, such as are used currently in the treatment of arthritis, renal insufficiency occurred, and in a child with rheumatoid arthritis who was given 100,000 units of ertron daily, a decreased calcium retention and an increased urinary excretion of calcium were noted. These observations further support the conclusion that large doses of vitamin D from any source are potentially toxic. This toxicity can be explained as being due to the effect on the calcium and phosphorus metabolism and on kidney function.

WALTER H. NADLER, M.D.

Brown, A.: The Ehlers-Danlos Syndrome. A Description of 3 Cases. *Glasgow M. J.*, 1946, 27: 7.

The syndrome characterized by hyperelasticity of the skin, hyperextensibility of the joints, and a hemorrhagic tendency was first described by Ehlers in 1899. Other men have since described it.

The skin in a typical case is fine and soft, like velvet. It may tear readily, and accidental injuries

or surgical incisions heal slowly and leave a papyraceous scar which is not adherent to the subadjacent tissues. Approximation of the edges of a wound is difficult to maintain because the sutures tend to cut out and a low grade infection often supervenes. Elasticity of the skin may be very much increased, especially on the upper part of the trunk, where the skin may be drawn out several inches from its original position, and it will return at once on being released. This hyperelasticity of the skin is to be differentiated from an unusually lax skin (cutis laxa), a second variety of loose skin. Hyperextensibility of the joints is a very variable and inconstant feature. It often involves the joints and it may be absent. Friability of the skin and a hemorrhagic tendency are not necessarily related features.

There is frequently a tendency for hematomas to develop after a trivial injury. Bleeding may or may not occur after an incision. Small nodules have been found in the subcutaneous tissue. At first glance, these seem to be composed of fatty cells surrounded by a dense fibrous capsule. Calcification may occur in them. The Ehlers-Danlos syndrome may show a hereditary element. The author gives 3 case reports with complete examination and the laboratory findings. He arrives at the following conclusions:

Two patients, a mother and daughter, showed hyperelasticity of the skin, hyperextensibility of the joints, and a hemorrhagic tendency. In four generations of their family, 19 of the 47 individuals were affected by a similar or closely related condition.

Among the affected members of this family, hyperelasticity was a minimal feature in the earlier, and a dominant feature in the later, generations. An unusual friability of the skin showed an inverse relationship.

A third case is described in which increased friability of the skin and subcutaneous tissues was associated with an almost entire loss of the body hair, a slight hyperelasticity of the skin, and a hemorrhagic tendency. These features developed when the patient was 53 years of age. There was no evidence of a hereditary element.

PAUL MERRELL, M.D.

Spelman, C. R.: The Protection of Feet Immersed in Cold Water. *U.S. Nav. M. Bull.*, 1946, 46: 169.

In feet maintained at temperatures below 12 or 14°C., hyperemia, swelling, and pain occurred quickly, but serious injury (immersion foot) did not occur rapidly at temperatures near the upper limit of this range. Feet maintained at an average temperature of 12°C. for 30 hours recovered quickly. By means of a thin layer (6.5 mm.) of good insulating material (with heat conductivity of 0.00015 cal./°C./cm./cm.²/sec.), feet immersed in ice water (0.5°C.) were maintained at a temperature of from 12 to 14°C., at which temperature immersion foot does not occur rapidly. However, very large quantities of insulation were needed to keep feet above the temperature at which immersion foot may occur if exposure was sufficiently prolonged (observations

were made on subjects who were sitting in the cold with legs dependent). When the body was kept warm, the feet, encased in the insulation described and immersed in ice water, remained much of the time above the temperature at which injury by cold occurs. Petrolatum did not appear to afford any great protection to feet immersed in cold water. Exercising the feet seemed of value and should be of aid in preventing immersion foot.

WALTER H. NAELER, M.D.

Barnett: Progress in Our Knowledge of Hydatid Disease. *N. Zealand M. J.*, 1945, 44: 304.

Of 1,828 records in the Hydatid Registry of the Royal Australasian College of Surgeons, 1,152 (65%) are grouped as cases of liver disease and secondary disease of the peritoneum and 451 (24%) as cases of lung disease. Liver disease and secondary peritoneal cysts of the abdomen and pelvis are classed under one heading because true primary peritoneal cysts are definitely rarities, less than 1 per cent, although many have been erroneously recorded as primary cases because the original primary location in the liver had not been recognized. It is remarkable how frequently rupture of a liver cyst into the peritoneal cavity escapes notice until multiple secondary cysts, or (as a surgical curiosity) a single heterotopic primary cyst, make themselves manifest many years after. The percentage of lung cysts in the Australasian Registry is 24 per cent, whereas the generally accepted figure in overseas literature is 12 per cent.

A study of the Registry gives proof also that the vast majority of primary cysts originate in childhood. It may be accepted as a fact that a juvenile primary cyst in an adult is of very rare occurrence, and that the aphorism of Deve, Dew, and others, that a hydatid cyst is nearly as old as its host, holds true.

It is the author's personal impression also that only a small proportion of children are susceptible to hydatid infection; otherwise, under conditions prevalent in hydatid countries the human incidence would be far higher than it is.

In a hydatid country like New Zealand one should remember that biliary colic and jaundice may be due to the opening of a hydatid cyst into the bile ducts. The usual laboratory tests should be supplemented in all suspicious cases by a careful examination of the feces for cyst fragments. One should look for bulging of the right lower part of the thorax: also for compensatory hypertrophy of the left lobe of the liver. The x-ray examination, too, may give conclusive evidence of a cyst bulging upward from the dome of the liver, and in old degenerated cysts, gases of putrefaction due to anerobic infection may bring about peculiar modifications of the light and shade levels.

The cysts of the dome of the liver, tucked away under the shelter of the lower part of the thorax, grow slowly and secretly for 10, 20, 30 years or more and may reach the size of an ostrich egg before they produce ill health. It is only in sensitive regions like the brain, spinal cord, and orbit that a simple un-

complicated cyst causes troublesome symptoms at an early stage. When a fissure or other damage of the parasitological membranes occurs, eroded bile ducts in the adventitia may leak into the cyst cavity and thus cause infection of low or high degree. In the case of the larger ducts the opening may be big enough to allow portions of bydatid membrane and perhaps daughter cysts to descend the ducts and even reach the duodenum, this descent being accompanied by spasmodic biliary colic and jaundice.

Cysts of the liver dome that cause trouble are likely to be large and bulge downward as well as upward, and the abdominal incision serves almost always quite as well as a transthoracic incision for their evaluation, although in difficult cases a prolongation of the incision vertically upward through 2 or 3 of the lower costal cartilages near the sternum is helpful. In rare cases the cyst is really inaccessible by the abdominal approach. It is well to bear in mind that these cysts are usually old with degenerated bile, and contaminated with more or less septic contents, and a study of the cases of this type in the Registry reveals that serious complications and fatalities are just about twice as frequent after the thoracic operation as after the abdominal operation. Pyopneumothorax, for instance, is very common and can be deadly. The pleura possesses a feeble, and the peritoneum a stronger, resistance to infection.

Deep seated lung cysts in young people should be given a chance at spontaneous cure. If, however, sepsis and toxemia become evident, and this is likely to happen if the associated bronchial fistula is small and high up in the cyst wall so that complete escape of the contents is difficult or impossible, operation is indicated. In cases of special difficulty a lobectomy is now advocated. For the common type of lung cysts the two stage operation seems to be favored, but in the author's opinion a one stage technique under high pressure intratracheal anesthesia is preferable. The adhesions produced by the packing, painting, or powdering in the first stage procedure are, more often than not, flimsy and ineffective. Exploratory tapping may be fallacious and dangerous. The injection of formalin solutions, even as weak as 1 or 2 per cent into lung cysts should be resorted to with caution because the frequent presence of bronchial fistulas may lead to alarming and sometimes dangerous respiratory troubles.

Cysts of the heart are extremely rare. In the Registry there were 6 examples. When they occur, they are not usually diagnosed in the curable stage. Sooner or later, if the patient lives long enough, metastatic cysts are carried in the circulation to distant parts and notably to the brain.

JOSEPH K. NARAI, M.D.

Reimann, H. A., Price, A. H., and Ellis, W. F.: Streptomycin for Certain Systemic Infections and Its Effect on the Urinary and Fecal Flora. *Arch. Int. M.*, 1945, 76: 269.

The authors have continued their studies of the clinical efficacy of streptomycin therapy in typical

fever. They report, in addition, the effects of this type of therapy as noted in cases of brucellosis, tuberculous meningitis, urinary tract infections, and on the flora normally present in the bowel.

Ten cases of typhoid fever treated with streptomycin therapy are summarized in this article. In 6 patients, definite improvement seemed to be attributable to the streptomycin. Two patients showed no improvement that could be ascribed directly to this drug, and 2 died. No improvement occurred in some instances in which the drug, given intravenously, was present in the blood stream in amounts far above the theoretical bactericidal level. No strict correlation could be obtained as to the concentration of streptomycin effective in vivo as compared to the blood level necessary for clinical improvement, when dealing with the same strain. Different strains of *Escherichia typhosa* showed considerable variation in their resistance to streptomycin. Further, the problem was complicated by irregularities in the levels of streptomycin attained in the body with similar dosages in the same patient and in different patients.

Only 1 of 3 patients suffering from brucellosis showed any apparent benefit from streptomycin therapy, although the blood levels obtained were many times the amount theoretically needed for bactericidal efficacy.

Massive doses of streptomycin, 4.0 gm. daily by continuous intravenous drip, were administered to a patient with tuberculous meningitis during the 7 days preceding death. No significant alteration in the spinal fluid or clinical course could be ascertained, although high streptomycin concentration was attained in the spinal fluid.

Parenteral administration of streptomycin promptly suppressed or eliminated the bacillus pyocyaneus, bacillus proteus morganii, and escherichia coli from the urine of several patients; however, therapy was effective only when these bacteria were strains susceptible to the amounts of streptomycin present in the urine. Similarly, the oral administration of streptomycin promptly suppressed or eliminated the escherichia coli and certain other bacteria in the feces during the period of administration, but failed to do so when the strains present were resistant to the concentrations of the drug present.

CLARENCE V. HODGES, M.D.

Parry, E.: Surgery in Malaria. *Lancet*, Lond., 1946, 250: 49.

Malaria may precipitate an acute emergency on the slightest surgical maneuver. The cases cited are of malignant tertian infection by the plasmodium falciparum.

Wounds of patients who suffer from malaria do not heal normally and have a tendency toward hemorrhage with the risk of secondary suppurative. Three cases reported had postoperative bleeding from a compound leg fracture, laceration of the neck, and pelvic fracture with bladder injury, respectively. In all of the cases the plasmodium falciparum was found in the blood stream, and

quinine, given intravenously, proved effective in preventing further hemorrhage. One case showed epistaxis, and in 2 cases bleeding occurred into thyroid adenomas. In another case, there was abdominal pain on the right side, not preceded by generalized pain. Appendectomy was performed and at operation congestion of the appendix and cecum was seen with numerous subserous petechial hemorrhages; postoperatively a large subcutaneous hematoma developed. In still another case postoperative bronchopneumonia was diagnosed, and the plasmodium falciparum was found in the blood stream. In the postmortem examination of 3 other patients who died from bronchopneumonia, the author found intense congestion of the lungs with the plasmodium falciparum in smears taken from these congested areas.

Hemorrhages, large or petechial, caused by malaria lead to confusion in the diagnosis, and may be the cause of complications after surgery. The prompt intravenous use of quinine in surgical cases is very valuable.

ARTHUR J. LESSER, M.D.

Chernoff, H. M., Evans, T. S., and Bartlett, C. J.: Extragenital Chorioepithelioma in the Male. *Arch. Int. M.*, 1945, 76: 347.

Chorioepithelioma is a rare tumor in the male, only about 200 cases having been recorded in the literature. There have been 5 cases reported in which, on adequate gross and microscopic examination of the testes, the tumor was shown to be extragenital in origin.

The authors present an additional case, that of a 30 year old white male who exhibited the clinical picture of a widely metastasizing tumor of embryonal urogenital origin: gynecomastia, lumbar pain, hemoptysis, loss of weight, and a rapid downhill course. Friedman tests of both the urine and spinal fluid revealed the presence of large amounts of gonadotropic hormone. Serial sections of both testes failed to reveal the presence of a primary tumor site. A large retroperitoneal mass in the region of the left kidney was believed to be the primary growth, and it is suggested that the tumor was derived from germinal epithelium in the region of the primitive urogenital anlage. Sections of several metastatic nodules showed the Langhans and syncytial cells typical of chorionic tissue.

CLARENCE V. HODGES, M.D.

Twombly, G. H., and Meisel, D.: The Growth of Mammalian Tumors in Fertile Eggs. Is a Filtrable Cancer Virus Produced? *Cancer Res.*, 1946, 6: 82.

In 1936 Bittner demonstrated for the first time that mammary cancer in the laboratory mouse is related in some way to a substance found in the milk. So-called low tumor strains could be made to develop cancer by feeding the young mice with milk derived from a high tumor strain mother, whereas the incidence of mammary cancer in high tumor strain females could be greatly reduced by foster nursing

them from birth with low tumor strain mothers. In a recent review of the milk influence Andervont concludes that "filtration and ultracentrifugation experiments show that it can be transmitted by cell-free material, and its transmission through many generations of mice implies propagation. These features suggest the action of an agent belonging or related to the viruses." Consequently, when Taylor published the results of experiments in which he had grown mouse mammary cancer successfully in fertile eggs, and then apparently demonstrated the presence of a filtrable viruslike principle in the surrounding yolk that would reproduce the tumor in a few days when injected into susceptible mice, the demonstration of a virus as causative agent of a mammalian tumor did not seem beyond the bounds of possibility according to accepted theory.

The authors attempted to repeat, confirm, and elaborate on Taylor's observations. Rat sarcoma R39, Bagg mouse carcinoma 755, and the RC mouse carcinoma of Taylor have been grown successfully in fertile incubated hen's eggs.

In the authors' opinion, the tumor producing capacity of egg yolk from yolk sacs in which mammalian tumors have been grown is due to the presence of viable tumor cells in the yolk. No convincing evidence of the presence of a virus or filterable agent has been encountered in their experiments.

JOSEPH K. NARAT, M.D.

Deza Cenget, D., and Socci, A.: Cutaneous Carcinoma Produced by Coal Tar, of Pilosebaceous Origin (Carcinoma cutáneo por alquitrán de hulla, de origen pilo-sebáceo). *Farm. biogéim.*, 1945, 1: 247.

The discovery of cancerogenic properties of certain chemicals is responsible for the fact that infectious and parasitic theories of cancer origin have been discarded. The cancerogenic property of certain substances is linked with the phenanthrene nucleus which is present in coal tar, coffee, tea, tobacco, products of distillation of oil, and luel oil. The coexistence of such chemical stimuli with certain biological factors is the necessary requirement for the origin of a neoplasm. Only in this manner can the complete resistance of certain species of animals to the development of cancer be explained.

A certain cycle may be observed in the modifications of tissues of malpighian origin, preceding the experimental formation of cancer, viz.: (1) hyperplasia, (2) hyperkeratosis, (3) papillomatosis, and (4) terminal cancerization. The first two groups represent preneoplastic modifications, while the last two belong to neoplastic lesions.

In contrast to initial epithelial hyperplasia, the author observed an atrophy of the malpighian epithelium which at times was of such intensity as to dominate the histological picture.

According to the German school of thought Krompecher's basocellular carcinoma is of the same origin as a cancer of hornified or spinocellular epithelium, both resulting from a neoplastic proliferation of the basal or germinative layer. According to

the French school, the basocellular carcinoma develops exclusively in the epithelial sheaths of hair follicles.

The authors' studies convinced them that the carcinoma of the epithelial layer produced by coal tar originates in the hair follicles.

JOHN K. NARAT, M.D.

Nocito, F. J.: Sarcoma of the Connective Tissue Spaces and of the Muscles of the Extremities (Sarcoma de los espacios conjuntivos y de los musculos de las extremidades). *Rev. Ar. med. argent.*, 1945, 59: 1291.

The author reports 17 cases of sarcoma of the connective tissue spaces and of the muscles of the extremities. Various names have been applied to this type of tumor, e.g., fascicular sarcoma, sarcoma fusocellulare, fibrosarcoma, conjunctivoma, and sarcoma of the vascular sheaths. The author prefers the term used in the title of his article because it does not indicate the exact origin of the tumor, which may develop in the fascia, fat, or the sheaths surrounding the blood vessels or nerves. Sarcomas of the skin, nerves, blood vessels, lymph glands, serous cavities, tendons, synovial membranes, and articular capsules are excluded from this group. Clinically, it is impossible to differentiate tumors of the muscles from those of interfibrillary connective tissue. The role of an acute or chronic trauma is frequently discussed in the literature, but an intrinsic predisposition is required for the development of a sarcoma following trauma. In some instances a trauma attracts attention to a pre-existing tumor.

Of 17 tumors observed by the author, 5 were located on the upper and 12 on the lower extremities. Of those on the upper extremity, 3 were located on the forearm, 1 was on the elbow, and 1 on the upper arm. Of the 12 tumors of the lower extremity, 3 were located on the lower leg, 6 on the thigh, 2 on the buttocks, and 1 was in the groin.

Muscular sarcomas may be located within or outside of the muscles, invading the adjoining tissues. The size of the tumors varies and may reach that of an adult's head. Invaded muscles usually assume an ovoid shape with the greater diameter parallel to that of the affected extremity. The consistency of the tumor varies, being hard in some cases, soft or fluctuating in others. Fibrous tumors usually have a firm consistency while myxosarcomas are usually rather soft or pseudofluctuating. The last mentioned variety may contain gelatinous zones caused by degenerative processes leading to the formation of pseudocysts which contain blood or brownish liquid.

Compression of the veins by tumor masses may produce edema involving the tumor and responsible for a pseudomyxomatous aspect. Intratumoral hemorrhages cause a pigmentary infiltration and melanotic aspect. Rhabdomyosarcomas are rare and when they invade the adjacent tissues. Some sarcomas contain zones of ossification or cartilaginous tissues because of the corresponding properties of

mesenchymal cells. Such tumors are called osteoblastic or chondroblastic fibrosarcomas, respectively.

One of the most important characteristics of sarcomas of the connective tissues is the capsule. In voluminous tumors the capsule may be defective, which facilitates invasion of the adjoining tissues. The clinical evolution and the histological examination do not support the benign appearance of the tumor created by the capsule. It should be remembered that the capsule does not form a defensive barrier.

There is a variety of infiltrating rhabdomyosarcoma in which it may be impossible to determine the extent of the tumor because the neoplastic mass infiltrates and dissociates the muscular fibers in a manner similar to epithelioma.

Important nerves such as the median or sciatic nerve may be invaded, which suggests the origin of the sarcoma to be from the nerve itself.

Invasion of the lymph glands is rare. Muscular fibers may be incorporated in the tumor mass and may show signs of fragmentation or other alterations produced by degenerative reactions which precede the neoplastic invasion.

From the histogenetic point of view the following classification may be offered: (a) Nondifferentiated sarcomas with mesoblastic cells, and (b) differentiated sarcomas: (1) fibroblastic sarcomas, (2) rhabdomyosarcomas, (3) lipoblastic sarcomas, (4) mixosarcomas, (5) angioblastic sarcomas, and (6) osteoblastic sarcomas.

The skin overlying the tumors may be freely movable or adherent to the tumor. Ulcerations are not infrequent. Ischemic processes may be responsible for the soft consistency of the large fibrosarcomas. The encapsulation explains a certain mobility of tumors. Muscular contractions usually immobilize the tumor, but this sign does not necessarily indicate that the neoplasm originated within the muscle because the same sign may be present in sarcomas located below the aponeurosis or between the muscles. Edema of the involved extremity is frequent, being caused by compression of the veins. Arterial compression is less frequent and is detectable by a diminution or suppression of the pulse.

As a rule regional adenopathies are not demonstrable. Compression of the nerves may cause pain, atrophy, or paralysis of the muscles. Exploratory aspiration, although recommended by the author, frequently gives negative results. X-ray examinations show no connection between the tumor and the skeletal system. Intratumoral opacities caused by calcification or ossification may be detectable. Chest roentgenograms should never be omitted because only by this means may pulmonary metastases be demonstrated.

The general condition of the patients remains good for a long time. Blood examination may show uremia or leucocytosis, especially if hemorrhage and infection are present. Fever may accompany cachexia.

Sarcoma may penetrate the skin and form a so-called sarcomatous fungus. Recurrence of the fibrous

tumors may appear several years after their excision while in other types of neoplasms recurrences usually develop at an earlier date.

Cough, hemorrhage, sputum and pain are late manifestations of pulmonary metastases, but the metastases are detectable earlier in roentgenograms.

The prognosis is bad in spite of a slow progress of the tumors, mobility, and the absence of pain. Sarcoma of the proximal portions of the extremity gives a poorer prognosis than that of distal portions. The larger the tumor the poorer the prognosis. The younger the age of the patient the more serious the prognosis.

Subaponeurotic location of the tumor, its independence from the bony structures, and a progressive growth are characteristic. Tumors of the tendon sheaths and serous cavities may be differentiated by their benign evolution and their location. Synovial cysts can be recognized by their periarticular location and smooth outlines; they may be reducible and of a remittent character. Benign and malignant tumors of the skeletal system may be recognized in roentgenograms. Chondromas are usually multiple. Osteogenic exostosis is hard and situated in the region of the metaphysis. Osteogenic sarcoma is found most frequently on the lower extremities, especially on the thighs; it is hard and painful. Solitary myeloma is deeply located, immobile, and recognizable in roentgenograms. Syphiloma may simulate a sarcoma. Serological examination usually clears up the diagnosis. The sclerosing form of muscular tuberculosis and infectious myositis are rare lesions of a diffuse character. Frequently a fluctuation is found. Sporotrichosis manifests itself in the form of multiple subcutaneous nodules adherent to the skin. Deeply located lipomas are soft or pseudofluctuating tumors which may be easily confused with sarcomas. Muscular angiomas are very rare. They are painful and compressible. Neurinomas are located along the trunks of large nerves, such as the median and sciatic nerves.

Biopsy may accelerate the growth of the tumor, and therefore should be performed only if a surgical intervention can immediately follow the histological diagnosis.

The following methods of treatment are available: (A) x-ray or radium therapy; (B) surgical procedures: (1) enucleation, (2) wide excision of the tumor with the adjoining tissues, (3) amputation or disarticulation; and (C) combined treatment consisting of preoperative irradiation followed by operation.

The results of surgical treatment are by far superior to those of irradiation therapy. Wide excision of the tumor preceded by irradiation may be recommended for tumors located in the distal region of the extremities. If extirpation of the tumor would probably interfere with the blood supply of the involved extremity, or if the surgeon is dealing with a recurrent tumor, a mutilating operation is indicated. In advanced cases a test irradiation may be employed: if the size of the tumor diminishes rapidly, irradiation should be continued because such tumors are

usually very malignant and the frequency of post-operative pulmonary metastases is great. If the tumor does not yield to irradiation, it should be removed. In inoperable cases, x-ray therapy is the only method of treatment.

JOSEPH K. NARAT, M.D.

DUCTLESS GLANDS

Sayers, G., Sayers, M. A., Tsan-Ying Liang, and Long, G. N. H.: The Effect of Pituitary Adrenotropic Hormone on the Cholesterol and Ascorbic Acid Content of the Adrenal Glands of the Rat and the Guinea Pig. *Endocrinology*, 1946, 38: 1.

The injection of highly purified adrenotropic hormone into rats and guinea pigs was followed by a prompt fall in the adrenal ascorbic acid, and a slower fall in the adrenal cholesterol. The levels of these substances in other tissues were not affected.

Following the injections, the adrenal cholesterol slowly returned to the initial level in 24 hours in both species. The rate of return of the adrenal ascorbic acid was quite rapid in the rat. In the guinea pig, the level remained depressed for some hours and then slowly rose, but the level was still subnormal 24 hours after the injection.

Coincidentally with the fall in adrenal ascorbic acid and cholesterol, there was an increased deposition of liver glycogen in both the rat and the guinea pig. These changes in adrenal ascorbic acid and cholesterol, under the influence of adrenotropic hormone, may be associated with the formation and release of the adrenocortical hormones.

SAMUEL KARR, M. D.

Astwood, E. B., Blissell, A., and Hughes, A. M.: Further Studies on the Chemical Nature of Compounds Which Inhibit the Function of the Thyroid Gland. *Endocrinology*, 1945, 37: 456.

The effect of 220 antithyroid compounds, orally administered in the diet, on hypertrophy and hyperplasia of the thyroid glands of rats was estimated by determinations of weight and iodine content of the glands by methods previously described. The results of a 10 day feeding period are plotted on a log dosage scale and compared with the effects of thiouracil, which are taken as the unit of activity. An example of one experiment with thiouracil is plotted and the effects of the other compounds are tabulated. The tables include the name and formula of the compound, its source, the number of tests conducted, the dose tested, the gain in body weight per day, the thyroid weight and iodine content, and the estimated activity of the compound compared with thiouracil. The compounds included 22 thiourea derivatives; 10 imidazoles and imidazoles; 18 thiazoles, thiazolines, and oxazolines; 17 mercapto or thio derivatives of 5 or 6 membered heterocyclic ring compounds; 15 other sulfur compounds related in one way or another to the compounds already mentioned; 9 thiopyrimidones; 46 thiouracil derivatives; 39 thiobarbituric acids; 28 aminobenzene derivatives; and 16 benzene derivatives lacking an amino on the aromatic ring.

Of the 220 substances tested, 115 had detectable activity and 25 were as active or more active than thiouracil. The most active were the thiouracil derivatives, and their activity is listed in decreasing order, taking thiouracil as unity: 6-n-propyl, 11; 6-benzyl, 10; 6-terthutyl, 9; 6-ethyl, 8; 6-sec-butyl, 6; 6-isohutyl, 5; 5-ethyl, 3.5; 5-methyl, 6-ethyl, 3.5; 6-n-butyl, 3; 5-isopropyl, 2.5; 5-n-propyl, 2; 5, 6-diethyl, 2; 5, 5-diethyl-2-thiobarbituric acid, 1.7; 2-mercapto-imidazole, 1.5; 2-mercaptothiazoline, 1.3; and 5-amino-2-mercapto 1, 3, 4-thiadiazole, 1.2.

Two types of chemical structure are found to be associated with antithyroid activity, the most active possessing a thiocarbonamide grouping and the least active an aminobenzene group.

Environmental temperature, humidity, and iodine intake were not controlled, but there was considerable agreement between the results of the authors and those of McGinty, Bywater, and Jenes (J. Pharmacol. Exp. Therap., 1945, 84:342; 85:11, 129) with regard to 20 compounds. These authors more carefully controlled the iodine intake and temperature in experiments in which some 120 compounds were tested.

CLINTON H. THRENS, M.D.

Goldzieher, J. W.: Pituitary Lesions Accompanying Obesity. *Arch. Path., Chic.*, 1946, 41: 203.

The pituitary glands of 10 patients who came to autopsy were studied. All of the patients had been extremely obese. Nine pituitary glands from persons who had no physical or historical evidence of past or present obesity and who corresponded closely in age and sex were used as controls.

In all 10 of the obese persons there was an increase of the basophilic cells of the pituitary gland. The change was marked in 6 and moderate in 4. The eosinophils were decreased in 2. There was a pronounced increase of the chromophobes in 5. Small adenomas of the gland were found in 4 obese patients. A peculiar relatively circumscribed scarring was found in 9 patients, being absent only in 1 patient. A marked increase in colloid was found in 3 obese patients and a moderate increase in 1 patient. Pronounced vacuolation of the basophilic cells was present in 6 cases of the obese group; in 3 others this change was present to a slight extent.

No changes similar to these were found in the 9 selected control cases.

Although the pituitary changes in these obese patients, consisting of this peculiar scarring of the stroma and a predominance of the basophils with some increase in the chromophobes, were striking, their causal relationship to the development of obesity was not determined.

The range of the twofold dilution series was from 1 in 5000 to 1 in 80,000. Figures show the highest dilution of mycophenolic acid which completely inhibited growth (x in ...). In most cases where complete inhibition is recorded at a low dilution there was also partial inhibition at higher dilutions.

*Where partial inhibition is recorded, growth was diminished but not totally suppressed at 1 in 5000 and usually at one or more higher dilutions also.

T. depressum appears in parentheses because its group is not determined.

T. cerebiforme and *T. pilicillae* are often classed separately in the neoendothrix group.

Dierckx (National Collection of Type Cultures No. 3568).

Serial dilution of sodium mycophenolate showed stronger action against the gram positive than against the gram negative organisms. There was apparently no destruction of mycophenolic acid by the bacteria, the majority of which proved sensitive to the antibiotic. Staphylococci could be proved to acquire resistance to mycophenolic acid at a fairly rapid rate—a 16-fold increase in resistance in the third culture. Serum reduced the activity of mycophenolic acid by less than 50 per cent.

Most of the leucocytes were killed immediately by a concentration of 1:200, but a dilution of 1:1000 showed no effect on their motility or survival. The intravenous medium lethal dose for mice of from 18 to 21 gm. was about 10 mgm., and organ studies in the mouse after different methods of administration—oral, subcutaneous, and intravenous—showed good absorption from the subcutaneous tissue and

upper gastrointestinal tract. Considerable destruction or inactivation of the antibiotic appears to occur in the body.

The antibiotic was effective against a number of saprophytic fungi and Table I summarizes the effect against pathogenic fungi. It also proved to be effective against a number of fungi and bacteria which are pathogenic to plants. Its antibacterial effects are greatly affected by the size of the inoculum. Mycophenolic acid is the first antibiotic produced by a mold known in crystalline form.

ARTHUR J. LESSER, M.D

Sanders, A. G.: The Effect of Some Antibiotics on Pathogenic Fungi. *Lancet*, Lond., 1946, 250: 44.

It appears possible that even some of the more toxic antibiotics may be harmless and effective when applied locally. This article describes results obtained in a survey of the antifungal properties of different substances, which were added to some 40

usually very malignant and the frequency of post-operative pulmonary metastases is great. If the tumor does not yield to irradiation, it should be removed. In inoperable cases, x-ray therapy is the only method of treatment.

The range of the twofold dilution series was from 1 in 5000 to 1 in 80,000. Figures show the highest dilution of mycophenolic acid which completely inhibited growth (1 in ...). In most cases where complete inhibition is recorded at a low dilution there was also partial inhibition at higher dilutions.

*Where partial inhibition is recorded, growth was diminished but not totally suppressed at 1 in 5000 and usually at one or more higher dilutions also.

T. depressum appears in parentheses because its group is not determined.

T. cerebriiforme and *T. pilicellula* are often classed separately in the neoendothrix group.

Dierckx (National Collection of Type Cultures No. 3568).

Serial dilution of sodium mycophenolate showed stronger action against the gram positive than against the gram negative organisms. There was apparently no destruction of mycophenolic acid by the bacteria, the majority of which proved sensitive to the antibiotic. Staphylococci could be proved to acquire resistance to mycophenolic acid at a fairly rapid rate—a 16-fold increase in resistance in the third culture. Serum reduced the activity of mycophenolic acid by less than 50 per cent.

Most of the leucocytes were killed immediately by a concentration of 1:200, but a dilution of 1:1000 showed no effect on their motility or survival. The intravenous medium lethal dose for mice of from 18 to 21 gm. was about 10 mgm., and organ studies in the mouse after different methods of administration—oral, subcutaneous, and intravenous—showed good absorption from the subcutaneous tissue and

upper gastrointestinal tract. Considerable destruction or inactivation of the antibiotic appears to occur in the body.

The antibiotic was effective against a number of saprophytic fungi and Table I summarizes the effect against pathogenic fungi. It also proved to be effective against a number of fungi and bacteria which are pathogenic to plants. Its antibacterial effects are greatly affected by the size of the inoculum. Mycophenolic acid is the first antibiotic produced by a mold known in crystalline form.

Sanders, A. G.: The Effect of Some Antibiotics on Pathogenic Fungi. *Lancet*, Lond., 1946, 250: 44.

It appears possible that even some of the more toxic antibiotics may be harmless and effective when applied locally. This article describes results obtained in a survey of the antifungal properties of different substances, which were added to some 40

species of fungi grown in a liquid medium (sterile glucose-peptone water, with a pH from 6.5 to 7.0). The cultures were obtained from the National Collections of Type Cultures and were grown on glucose agar for from 2 to 4 weeks. Small and equal pieces of mycelial felt were then placed into tubes containing the antibiotic and were incubated at 24 degrees C. for about 6 weeks; they were inspected at intervals of from 7 to 10 days. The antibiotics were also tested in serial dilutions ranging from 1:5000 to 1:160,000, and in the case of the little soluble gliotoxin, from 1:140,000 to 1:1,000,000.

No inhibition of growth was noted with penicillin (100 units/c.cm.) and helvolic acid (1:5500). Penicillic acid (1:5500) delayed the growth of 9 of 20 species tested, but lost activity rapidly during incubation. Gliotoxin (1:140,000) showed complete inhibition for 5 species, retardation for 11, and no inhibition for 10 species; however, it appeared to be unstable under these conditions. Aspergillic acid (1:5000) and cheiroline (1:5000) both completely inhibited the growth of all 37 species examined and possibly would repay further investigation. Results with mycophenolic acid are published separately.

Kinney, T. D., Haynes, F. W., and Dexter, L.: Experimental Production of Pulmonary Embolism by the Use of a Venous Catheter. *J. Lab. Clin. M.*, 1945, 30: 1015.

Methods for the experimental production of pulmonary embolism fall into two groups: embolism and ligation. The method most commonly employed has been the introduction of various kinds of foreign

bodies into the peripheral venous system. Its disadvantage is that the site of lodgment cannot be controlled and the ultimate action and effect on the lung cannot be predicted. Direct ligation has the disadvantage that the thorax must be opened and there is consequently a disturbance of the pulmonary and cardiac dynamics.

The method described consists in the introduction into the jugular vein of a number 8 or number 11 catheter 60 centimeters long with the tip bent at an angle of about 60 degrees. Under direct fluoroscopic examination the catheter is directed down the vein through the superior vena cava and into the right auricle. The catheter is manipulated into the right ventricle and into the pulmonary artery, and once in the artery it is possible to direct it into the right or left branch and into the smaller ramifications if so desired. The position may be ascertained with certainty by observing the tip of the catheter to be outside of the cardiac shadow. When in position, emboli may be injected directly into the pulmonary circulation. The method does not produce damage to the linings of the vessels or the heart.

Japan wax was used as a medium for studying the location of the embolus because its melting point is low and it readily congeals at the body temperature of the dog. The extent of the pulmonary vascular bed deprived of its blood supply can be readily controlled by the amount and type of embolic material used. An example obtained by using Japan wax showed the embolus to be in the form of a cast of the pulmonary artery and was reminiscent of emboli seen in massive pulmonary embolism in man.

THE FATE OF PRESERVED HETEROGENEOUS GRAFTS OF FASCIA WHEN TRANSPLANTED INTO LIVING HUMAN TISSUES

JACOB CHANDY, M.B., B.S., M.Sc., Philadelphia, Pennsylvania

THE importance and significance of the use of heterogeneous preserved fascia, especially in plastic surgery, have commanded the attention of many investigators. This present study is concerned with the changes which take place when preserved ox fascia is placed in contact with living human tissue. Such grafts have been studied over periods up to 4 years.

As soon as the animal was killed, the deep fascia was removed, aseptic precautions being used, and the grafts were placed in a solution of 70 per cent ethyl alcohol. While immersed in the alcohol the fascia was cleaned and cut into 2 inch by 2.5 inch pieces and finally transferred into absolute alcohol. After 2 weeks the pieces were considered available for use.

The prepared pieces of fascia were implanted into human tissue during various operative procedures, especially operations for hernia as advocated by Harrison. The implants were removed at subsequent reoperations at intervals up to 4 years in duration.

Specimen 1 is a section of normal preserved ox fascia before implantation into human tissue. Well preserved fibrous tissue is evident. Note that the nuclei are readily seen. The cell outlines are clear, and the cells are arranged uniformly. Blood vessels are not visible. The compact nature of the fascia is evident.

Specimen 2 is a section of preserved ox fascia 1 week after implantation into human tissue. Very little change is noted. A few leucocytes are seen infiltrating the periphery. No foreign body reaction is seen. The fascial structure is preserved.

Specimen 3 is a section of preserved ox fascia 2 weeks after implantation into human tissue. No marked change is seen in the ox fascia, except that more leucocytes are present at the periphery and fibroblasts are beginning to infiltrate into the graft.

Specimen 4 is a section of preserved ox fascia 3 months after implantation into human tissue. The well defined cell outlines and staining characteristics have changed. There is evidence of absorption at the periphery. Fibroblasts are observed growing into the graft, and capillary growth is also seen. The uniformity of arrangement of the fascial fibers is being changed to an arrangement in bundles, and more cells are seen between these bundles.

Specimen 5 is a section of preserved ox fascia 8 months after implantation into human tissue. There is observed a progressive change in that more fibroblastic growth into the graft is further defining the bundles seen in specimen 4. There is more absorption by the migrating cells at the periphery. No evidence of a foreign body reaction is seen.

Specimen 6 is a section of preserved ox fascia after 2 years of implantation into human tissue.

THE FATE OF PRESERVED HETEROGENEOUS GRAFTS OF FASCIA WHEN TRANSPLANTED INTO LIVING HUMAN TISSUES

JACOB CHANDY, M.B., B.S., M.Sc., Philadelphia, Pennsylvania

THE importance and significance of the use of heterogeneous preserved fascia, especially in plastic surgery, have commanded the attention of many investigators. This present study is concerned with the changes which take place when preserved ox fascia is placed in contact with living human tissue. Such grafts have been studied over periods up to 4 years.

As soon as the animal was killed, the deep fascia was removed, aseptic precautions being used, and the grafts were placed in a solution of 70 per cent ethyl alcohol. While immersed in the alcohol the fascia was cleaned and cut into 2 inch by 2.5 inch pieces and finally transferred into absolute alcohol. After 2 weeks the pieces were considered available for use.

The prepared pieces of fascia were implanted into human tissue during various operative procedures, especially operations for hernia as advocated by Harrison. The implants were removed at subsequent reoperations at intervals up to 4 years in duration.

Specimen 1 is a section of normal preserved ox fascia before implantation into human tissue. Well preserved fibrous tissue is evident. Note that the nuclei are readily seen. The cell outlines are clear, and the cells are arranged uniformly. Blood vessels are not visible. The compact nature of the fascia is evident.

Specimen 2 is a section of preserved ox fascia 1 week after implantation into human tissue. Very little change is noted. A few leucocytes are seen infiltrating the periphery. No foreign body reaction is seen. The fascial structure is preserved.

Specimen 3 is a section of preserved ox fascia 2 weeks after implantation into human tissue. No marked change is seen in the ox fascia, except that more leucocytes are present at the periphery and fibroblasts are beginning to infiltrate into the graft.

Specimen 4 is a section of preserved ox fascia 3 months after implantation into human tissue. The well defined cell outlines and staining characteristics have changed. There is evidence of absorption at the periphery. Fibroblasts are observed growing into the graft, and capillary growth is also seen. The uniformity of arrangement of the fascial fibers is being changed to an arrangement in bundles, and more cells are seen between these bundles.

Specimen 5 is a section of preserved ox fascia 8 months after implantation into human tissue. There is observed a progressive change in that more fibroblastic growth into the graft is further defining the bundles seen in specimen 4. There is more absorption by the migrating cells at the periphery. No evidence of a foreign body reaction is seen.

From the Mission Hospital, Bahrein, Persian Gulf.

sue. The fibroblasts of the host have grown into the graft very well. Cell outlines in the original graft are largely lost. Capillary invasion is marked, but the transplanted fascia can still be readily identified. There are more leucocytes and migratory cells at the periphery than in specimen 5.

Specimen 7 is a section of preserved ox fascia after 4 years of implantation in human tissue. Good capillary growth is evident at the periphery. A network of collagen fibers and fibroblasts has grown into the fascial graft completing the division into bundles. The nuclei of the original fascial fibers have disappeared. Note the absorption of the peripheral bundles and their extensive replacement by collagen fibers. The preserved tissue can still be easily distinguished from the living tissue.

OBSERVATIONS

The most evident features are:

1. The preserved ox fascia can be identified after 4 years of implantation in human tissue.
2. There is a very slow change in the character and nature of the preserved fascial fibrous tissue cells.

3. There is an abundant growth of capillaries and fibroblasts from the periphery into the fascial graft and complete absorption of the preserved fascial cells at the periphery.

4. The absorption of the cellular detritus of the preserved fascia is noted.

5. The fibers of the preserved fascia become rearranged into bundles as more fibroblastic and capillary ingrowth takes place.

6. There is relatively little leucocytic infiltration at the periphery of the graft and between the bundles.

7. There is no marked foreign body reaction, and giant cells are absent.

DISCUSSION

The use of dead material as grafts has been based principally on the work of Nageotte and Sencert (13, 14, 15). Nageotte (11) in 1916 formulated a theory of the nature and origin of connective tissue. He believed that albuminoid coagula are first formed from the parenchymal cells, that these coagula should not be regarded as living, and that their origin is similar to the formation of blood plasma. He called this coagulum "the fundamental sub-

Fig. 1.

Fig. 2.

stance," and he believed that it was composed of elementary collagen fibrils which give rise to collagen fibers, and that connective tissue is formed by the penetration of fibroblasts into the meshes of these fibers. The distinctive feature of Nageotte's theory is that he insists upon the fundamental nonliving character of all connective tissue substances. Baitzell's (2, 3) work supports Nageotte's conclusions. The other theories held regarding the formation of connective tissue are that it is made up of transformed portions of the exoplasm which comes from a syncytium of mesenchyme cells and also that the early syncytium of the mesenchyme cells secretes an amorphous gelatinous nonliving ground substance in which the connective tissue fibers form. Baitzell (4) observed also the direct transformation of fibrin clot into connective tissue fibers. Tissue cells which grew into the fibrin clot developed into fibroblasts.

Nageotte believed that, since connective tissue substances are inert coagula formed from living cells, one would not expect grafts of such tissues to act as foreign bodies and induce phagocytosis, and similarly connective

Fig. 3.

Fig. 4.

Fig. 5.

Fig. 6

Fig. 7.

tissue preserved in alcohol, since they have the same nonliving origin, should not produce phagocytosis and foreign body reaction. In other words, reaction to preserved fibers should be the same as that to living ones. He explained the results of his experiments on the theory that the nonliving graft takes and becomes adherent; that it soon becomes impossible to determine its limits because the union between the living and nonliving tissue has effected itself so perfectly. In his experimental studies the microscopic examination showed that the implanted graft blended with the living tissue until no line of demarcation could be detected. After the protoplasm of the cells of the preserved graft had been carried off by the migratory cells, or wandering macrophages, new fibroblasts from the host flocked into the persisting connective tissue framework of the graft and established themselves in the place of the old inhabitants. Circulation became established by the growing in of small vessels from the host, and in time it was actually impossible to tell that the graft has been dead when it was implanted. Nageotte called this process the "reviviscence." The

only phagocytosis which he was able to observe was that which was necessary for the removal of protoplasm of the preserved graft. Nageotte grafted, with success, cartilage, tendon, segments of arteries, and nerves.

Nageotte (12) and Sencert (17), Auvray, Dustin, Jalifier, Christophe, and many others have grafted successfully preserved animal tendon, nerves, and even an entire patella with good results.

The animal experiments of Koontz are of significance in this connection—heterogeneous and homogeneous grafts did not show any difference—they both healed and did not show any intolerance of the host tissues for the graft. Koontz believed that the preservation of the graft in alcohol eliminates the antagonistic action of foreign protein. It is an important fact that fibroblasts did not grow around the grafts at any time in sufficient numbers to produce encystment. No foreign body reaction was noted by Koontz. He concluded that after a period of a few months it would be impossible to distinguish the living from the preserved tissue graft after that had been transplanted into living connective tissue.

The results of the experimental work of Hass agreed very closely with those of Koontz. He showed that the transplanted preserved fascia united firmly with the muscle and did not tend to take the form of tendinous structures as the live graft usually did. Microscopically close intermingling of the muscle and the transplanted fascia was observed. There was no evidence of a foreign body reaction. There was no difference between the union of preserved fascia with the muscle and that of living fascia. Muscle cells appeared to be transformed into the elements of fibrous tissue and aided in the uniting process.

Rosenblatt and Meyers found very good union between preserved fascia and living tissue although they noted some foreign body reaction around the graft. They believed that the fascial graft acted as an element for substitution of connective tissue and was in part absorbed.

There is no evidence in the observations reported in the present study to support Nageotte's theory of the nature and origin of connective tissue. From the data obtained in my experiments it is clear that the preserved tissue does not in itself become a living tissue at any time although the value of the preserved tissue is quite evident. When a tissue is dead, its intracellular chemistry changes, and the devitalized material is absorbed and replaced by other tissue cells. The absorption may be slow if the material has been fixed in alcohol. The amount of foreign body reaction depends on the chemical and physical nature of the foreign body; and since fixed connective tissue cells are not irritating, they need not produce such a reaction. However, there occurs sufficient phagocytosis for the absorption of the foreign cellular detritus. This is well seen in the sections.

It may not be advisable to use the expression that preserved tissue unites or heals with living tissue, as used by Nageotte, Koontz, and others. It remains an integral part for a long time but eventually is replaced, at least

to a considerable extent, by living fibroblasts to form new connective tissue.

The importance of such preserved fascia lies in the fact that it can be used in various plastic surgery procedures as a framework into which normal tissues may grow. It has sufficient strength to serve in place of normal tissue for long periods of time, and it rapidly becomes firmly attached to these tissues in man.

SUMMARY

A study of the fate of preserved heterogeneous grafts of fascia when transplanted into living human tissue is reported. Such grafts have been observed and studied over a period of 4 years.

The preserved fascia rapidly becomes adherent to the human tissues and remains so for a long period of time. It is gradually replaced by the ingrowth of fibroblasts and capillaries and the formation of human connective tissue. This process was still incomplete, however, after 4 years.

A short review of the experimental studies in fascial transplants is given.

Photomicrographs of sections of preserved ox fascia after periods of from 1 week to 4 years in living human tissue are presented.

The advantage of preserved ox fascia in plastic surgical work is emphasized.

PERITONITIS OF APPENDICEAL ORIGIN TREATED WITH MASSIVE DOSES OF PENICILLIN

Report of 50 Cases

GEORGE CRILE, Jr., M.D., F.A.C.S., Commander, M.C., U.S.N.R., Cleveland, Ohio

THE purpose of this article is to report a group of 50 cases of proved peritonitis of appendiceal origin which were treated with large doses of penicillin over a long period of time. The peritonitis was controlled in all cases and all intra-abdominal masses resolved spontaneously without drainage. The dosage of penicillin was 100,000 units given every 2 hours, intramuscularly, for 2 to 6 days, followed by smaller amounts for 3 to 4 days.

REVIEW OF LITERATURE

In spite of the fact that penicillin has been widely used in the treatment of peritonitis, little has been written on this subject. Craig and others report 7 cases of peritonitis in which 20,000 units of penicillin was given every 2 hours with good results in the majority of the cases. There is no report in the literature of a series of cases of peritonitis treated with large doses of penicillin given over a long period of time. Yet in 1944, Fauley and others reported that in dogs peritonitis induced by ligation of the blood supply of the appendix could be controlled by the administration of penicillin in doses equivalent to 22,500 units per hour given to a 150 pound man over a period of 7 days. The mortality in untreated controls was 92.6 per cent; the mortality in those treated from the time of operation was 0 per cent, and the mortality of those treated after 12 hours was 21 per cent.

It has been established by the work of Ory and others that penicillin given parenterally enters the serous cavities of the body and is present in ascitic fluid in approximately the same concentration as in the blood (7). Loewe and others, moreover, have established that the level of penicillin attained in the blood is almost directly proportional to the dosage of penicillin given intramuscularly or

intravenously. When 100,000 units of penicillin is given intramuscularly the level in the blood rises to 1.7 units per cubic centimeter of blood 30 minutes after the injection, falls to 0.8 unit 60 minutes after the injection, and to 0.3 unit after 120 minutes. Craig and others state that a level of 0.02 unit per cubic centimeter is effective for the control of most organisms sensitive to penicillin. It is thus apparent that when 100,000 units of penicillin is given every 2 hours, the lowest levels, occurring just before the next injection, are still over 10 times in excess of minimal effective levels, and the maximum levels are over 80 times as high. There is reason to believe that it is necessary to maintain these high levels over a long period of time if peritonitis secondary to appendicitis or perforation of the colon is to be controlled.

CLINICAL MATERIAL

Definition of peritonitis of appendiceal origin.
From November 1, 1944, to November 1, 1945, at the U.S. Naval Hospital, San Diego, over 900 appendectomies were performed. In approximately 70 per cent of these cases, true acute appendicitis was present. In a little over 5 per cent of the cases, peritonitis was found. It is this group of patients, with peritonitis of appendiceal origin, with which this paper is concerned.

For this study no case was accepted as peritonitis of appendiceal origin unless at the time of operation an established purulent peritonitis or appendiceal abscess was present. Cases in which the appendix was ruptured in its removal but in which there was no evidence of an established peritonitis were eliminated.

If operation was deferred and the peritonitis was treated conservatively, such a case was not included unless there was strong clinical evidence of peritonitis subsequently

proved by the development of a palpable mass or by an interval operation confirming the presence of a gross perforation of the appendix. Also excluded from this group were patients who did not develop a mass and who either did not have an interval appendectomy or whose appendix at the time of appendectomy failed to show gross evidence of perforation.

Twenty-five of the 50 patients in this group were considered on clinical grounds to have generalized and 25 to have localized peritonitis. In 8, definite abdominal masses were palpable at the time of admission and in 25, pelvic or abdominal masses were palpable at some time during the course of the illness. All of the patients were sick, and it is clear that their illnesses represent the most serious complications of appendicitis.

The following information concerning the 50 cases of proved peritonitis is of importance: The average temperature on admission was 102.6 degrees, with a high of 105 and a low of 100. The average pulse on admission was 109, with a high of 130 and a low of 90. The average white blood count on admission was 17,000, with a high of 30,000 and a low of 5,000. The average duration of illness prior to entry was 3.2 days. There were 25 patients with general peritonitis, 25 with localized peritonitis, 8 in whom a mass was palpable on admission, 25 in whom there was a palpable mass at some time (15 pelvic and 10 abdominal). Conservative treatment of peritonitis was carried out in 23¹ patients, exploratory operation without appendectomy in 5, immediate appendectomy in 22.

The average duration of the illness before admission of patients subjected to appendectomy was 2.9 days, and of those treated conservatively, 3.8 days. In only 2 cases were the symptoms over a week's duration. Treatment, if any, prior to entry, had consisted in a small percentage of cases, of the administration of sulfonamides and in 2 or 3 instances of small amounts of penicillin. In 5 cases sulfanilamide was placed in the peritoneal cavity at the time of operation, and in 1 case 200,000

units of penicillin solution was left in the abdomen.

A McBurney incision was used in all but 4 of the cases. The stump of the appendix was not inverted, and fine cotton or catgut was used for closure of the abdominal wall.

TREATMENT OF PERITONITIS

Penicillin. As soon as the diagnosis of peritonitis was made, all patients were given 100,000 units of penicillin every 2 hours intramuscularly in procaine solution or by continuous intravenous drip. This treatment was continued until signs of improvement appeared. The longest course of this dosage of penicillin was 10 days, the shortest was 1 day, and the average was 3½ days. In the beginning of the period in which these cases appeared, when penicillin was scarce and costly, every effort was made to use as little as possible and the dose was usually halved after the first day. Later it was found more economical to give the larger doses for at least 3 or 4 days and then to continue with 50,000 units every 2 hours or 100,000 units every 4 hours for at least 3 more days. If the large doses were discontinued too soon, recurrences of the peritonitis were apt to appear or the patient developed a localized mass. A second course of penicillin would again result in the subsidence of all symptoms and signs of peritonitis and in the ultimate resolution of the mass (Fig. 1).

In the early days of this experience with penicillin, an attempt was made to set up a standard treatment for all cases. One hundred thousand units was given every 2 hours for the first day, then 50,000 units every 2 hours for 2 days, 50,000 units every 4 hours for 2 days, and finally 25,000 units every 4 hours for 2 days. On several occasions there were recurrences of elevation of temperature and of the symptoms and signs of peritonitis while the patient was still receiving 25,000 units of penicillin every 4 hours. The schedule was changed therefore, and the full dosage was maintained until the clinical signs of peritonitis subsided or until the patient had been on 100,000 units of penicillin every 2 hours for at least 6 days. Four days was sufficient to control the average case, and if satisfactory improvement occurred, the dosage

¹In all but 3 cases, interval appendectomy confirmed the presence of a gross perforation of the appendix. In the other 3, operation was not performed, but diagnosis was established by the development of a definite mass in the right lower quadrant.

Fig. 2. Localized peritonitis, 2 days' duration, with mass in right lower quadrant. All symptoms and signs subsided on treatment with penicillin. Recurrence when dosage was reduced to 25,000 units every 4 hours. Mass, fever, and symptoms permanently controlled with second course of 100,000 units of penicillin every 2 hours.

was reduced to 100,000 units every 4 hours. Fifty thousand units every 2 hours maintains a better level in the blood, but after 4 or 5 days the patients complain about the injections, and since by this time they are usually feeling much better, it is sometimes difficult to keep their co-operation. It is unwise, however, to discontinue large doses of penicillin on at least a 4 hour schedule before the sixth day of treatment, and sometimes 10 or 12 days may be required before large intra-abdominal masses begin to resolve.

The dosage, 100,000 units every 2 hours, is an arbitrary one and may be higher than required for some, and lower for others. Several patients responded well to 50,000 units every 2 hours, and 1 patient responded slowly to doses of 200,000 units every 2 hours. At least 3 patients receiving 30,000 units every 3 hours showed evidence of the spread of peritonitis or developed recurrences of localized masses with rising temperature and pulse rates when the dosage was lowered to this level. Similarly, several patients who had responded dramatically to large doses of peni-

cillin developed recurrences of their peritonitis when the administration of penicillin was discontinued after 1 or 2 days. In all of these cases the disease was again controlled by the prolonged administration of 100,000 units every 2 hours. Since side effects appear to be no more common when large doses are used than when the usual ones are given, and since the drug is now relatively inexpensive, it would seem safer to err on the side of overdosage. This point of view is supported by experiences in the treatment of sulfonamide or penicillin-resistant gonorrhea, in which studies it has been observed that if inadequate doses are at first given, a resistant strain of gonococcus is apt to develop (3).

There is reason to believe that certain of the commercial preparations of penicillin contain more of the fraction X than others. This fraction is from two to eight times more effective against the hemolytic streptococcus, the gonococcus and other organisms than is the fraction G, although its efficacy against the standard test organism, staphylococcus, is the same (8).

At one time, in this series, there was a group of 14 cases which did not respond as well as the previous cases had, and in checking back it was found that the brand of penicillin had been changed. At the same time, on another service, there was encountered an extraordinarily high percentage of penicillin-resistant cases of gonorrhea. When a different brand of penicillin was used, the penicillin-resistant cases obtained good results. One patient with peritonitis, resistant to the first brand of penicillin, responded promptly to a course of treatment with the second. Five brands of penicillin in all have been used in this series, and all but one have proved satisfactory.

Position. No attempt was made to maintain Fowler's position unless abdominal distention or dyspnea rendered the patient more comfortable in this position. Bed rest was insisted upon until the patient became afebrile.

Diet. Clear fluids were allowed *ad lib.* from the time of entry unless the patient was distended or vomiting. If the patient was unable to take adequate fluids by mouth or if distended, 5 per cent glucose in water or saline was given intravenously to make a total intake of 3,000 cubic centimeters daily.

Gastric suction. Continuous gastric suction was used in patients who were distended or vomiting. The amount of fluid and salt lost by suction was estimated and replaced parenterally. Patients were allowed to drink clear fluid.

Miller-Abbott tube. If gastric suction failed to decompress the abdomen or if the returns from the stomach indicated that ileus was present, a plain plate of the abdomen was taken. If this showed the slightest evidence of small intestinal obstruction, a Miller-Abbott tube was passed without delay. As soon as the Miller-Abbott tube passed the pylorus, the patient was allowed to take clear fluids, and when the tube had entered the ileum a soft diet was given.

It was not found necessary or desirable to use hot stupes on the abdomen. None of the patients in this group was seriously ill more than 4 days, and none went more than 4 days without taking food by mouth. For this reason, the glucose was not supplemented with amino acids. Since the plasma proteins did

Fig. 2. Composite temperature chart of 21 consecutive cases of peritonitis treated with large doses of penicillin.

not fall and since edema occurred in no case, plasma was not necessary. In no instance did anemia below 65 per cent hemoglobin occur, and no transfusions were given. The leucocytes showed little alteration during the febrile part of the illness and rechecked leucocyte counts while the patients were still ill, averaged 16,000 as compared to 17,000 on admission. In no instance did the leucocytes fall below 5,000 and almost without exception immature forms and toxic granulations decreased. One patient entered the hospital 3 days after an appendectomy for a perforated appendix. At the time of admission his temperature was 105, pulse 120, and he had classical signs of a generalized peritonitis. His white blood cells were only 5,000 and the differential blood count showed a marked leucemoid reaction, with 6 myeloblasts, 2 premyelocytes, 14 myelocytes, 11 juveniles, 13 band forms, 33 segmented forms, 11 lymphocytes, 8 questionable myeloblasts, and 2 unclassified cells. The leucocyte count rose steadily and the leucemoid reaction subsided following the administration of large doses of penicillin.

Oxygen was not used and distention was controlled, when necessary, by gastrointestinal intubation.

Fig. 3. Appendicitis of 2 days' duration. Appendectomy with finding of diffuse peritonitis. Peritonitis controlled with large doses of penicillin. Five days after penicillin was discontinued symptoms recurred and large mass, palpable by both rectal and abdominal examination, filled the pelvis. Second course of penicillin resulted in resolution of mass.

COURSE OF PERITONITIS

The course of the peritonitis in these 50 cases differed in several striking respects from that seen prior to the use of penicillin. The patients did not appear sick after the first 2 days. In no instance did the peritonitis appear to spread after the first 24 hours of treatment, and in all cases but one, definite clinical improvement had occurred by the fourth day. The abdomen lost its exquisite tenderness after the second day, and rigidity simultaneously disappeared. Distention was not often seen and ileus was minimized. Many of these patients did not vomit and were able to take a full liquid diet throughout the course of the disease. Most of them were alert, read magazines or newspapers, and did not seem to be uncomfortable.

Temperature. In no instance did the temperature or pulse rate rise higher after the first 2 days of treatment. In 50 per cent of the cases the temperature was normal by the end of the fifth day of treatment. The average febrile period for the entire group was 8 days before the temperature failed to rise over 99 for a 24 hour period. Nine patients ran a low-

grade fever, fluctuating from normal to 100 for over 10 days, and 1 patient remained febrile for 21 days. In the latter case a drain had been left in the pelvis and there was a profuse purulent drainage and wound infection, but the temperature did not rise over 100. A composite temperature chart of the first 21 cases treated with large doses of penicillin is depicted in Figure 2. The temperatures of the last 29 cases reached normal in exactly the same number of days as the first group, but their charts were not available for incorporation in the graph.

Pulse rate. One of the characteristic signs of uncontrolled peritonitis is an elevation of the pulse rate out of proportion to that of the temperature. Yet in this group the highest recorded pulse rate of the day had fallen below 100 by the third day (average) and in only 4 instances did the pulse rate remain over 100 longer than 1 week.

Ileus. Most patients with peritonitis experience considerable ileus, become distended, vomit, or put out large amounts of green or brown material by gastric suction. The majority in this group did not show signs of pro-

nounced ileus, or if they did so, it was only for a day or two. One explanation of this phenomenon is that penicillin controls the invasive qualities of the bacteria and minimizes the tendency to produce a paralytic type of ileus. This absence of cellulitis likewise may explain the rapidity with which the tenderness and rigidity of the abdomen subsides. The relatively slight amount of ileus and the consequently minimal loss of fluid and chlorides renders these patients easy to keep in fluid and chloride balance. Few alterations in blood chlorides were observed.

Despite the low incidence of paralytic ileus, true mechanical obstruction of the small bowel was fairly common. In 13 cases there was x-ray and clinical evidence of obstruction and in 12 of these 13 cases the obstruction was associated with the presence of a palpable mass. It is thus probable that the ileus was the result of mechanical obstruction in an inflammatory mass rather than secondary to the paralytic action of a generalized peritonitis. In every case the passage of a Miller-Abbott tube corrected the obstruction and in only 1 instance did it recur and require a second decompression.

Masses. During the acute stage of peritoneal irritation there is often so much rigidity that it is impossible to determine whether or not a mass is present. In only 8 cases was a definite mass palpable at the time the patient entered the hospital. But at one time or another during the course of the disease, 50 per cent of the patients developed intra-abdominal masses, 15 patients developed a pelvic mass palpable only by rectum and 10 developed masses easily palpable through the abdominal wall. All of these masses were located in the lower abdomen.

It has been estimated by Ochsner and Johnston that in cases of appendiceal peritonitis treated conservatively, three-fourths will subside spontaneously without going on to abscess formation (6). These authors state that in the remaining 25 per cent, incision and drainage of the abscess will be necessary. In this series of 50 patients, 26 were treated without appendectomy or drainage of an appendiceal abscess, 23 of these having had no operation and 3 having been merely explored.

Fig 4. Secondary rise of temperature due to penicillin. Slow pulse and prompt return to normal of temperature curve occurred as soon as administration of penicillin was discontinued.

In 15 patients a mass developed, but under treatment with 100,000 units of penicillin every 2 hours, 4 to 8 days, they became afebrile and free of symptoms; the masses lost their tenderness, became smaller, and eventually disappeared. In no instance were incision and drainage necessary and insofar as it was able to be determined, there was no instance in which pus was discharged spontaneously into the bowel. In several patients, symptoms recurred after being once controlled, and the mass became larger after treatment with penicillin was discontinued, but in each a second course of treatment resulted in a second remission and eventually in complete resolution of the mass. Figure 3 depicts the temperature chart of a patient who required a second course of penicillin to control a pelvic mass.

Some of the masses were so large as to cause a visible asymmetrical deformity of the abdomen or to fill the pelvis so completely that on rectal examination the rectum appeared to

Fig. 5. Localized peritonitis with mass in right lower quadrant and pelvis. No operation. Patient apparently refractory to second course.

be occluded. In 2 instances fluctuation could be detected by rectal examination, and attempts were made to provide drainage by forcing a passage through the rectal wall. Unlike the usual pelvic abscess when such a passage is accomplished with ease, it was found that the tissues were not friable and that the wall of the rectum was so normal as to render difficult the passage of finger or instrument. The attempt was therefore abandoned, and the fluctuant area gradually disappeared and the mass resolved. Passage of pus was never detected.

Another remarkable finding about the masses is the absence of acute tenderness. They are sensitive to deep pressure, but when they are resolving they present few of the features of an appendiceal abscess. In the case of one man in his fifties, the absence of tenderness and the presence of a hard fixed mass in the right lower quadrant led to the suspicion that the peritonitis had originated from a carcinoma of the cecum. Subsequently, it was proved that the appendix was perforated.

In 7 cases, intra-abdominal masses developed following appendectomy. Rogers and Faxon encountered 40 such cases at the Massachusetts General Hospital. In 50 per cent of these patients the masses resolved spontaneously, 16 required abdominal drainage, and 4 required rectal puncture. Four pa-

tients died. None of the 7 patients in this series required drainage and all resolved spontaneously. In 1 or 2 instances other than these 7 cases there may have been spontaneous drainage of small amounts of pus from the abdominal cavity through the wound but it was not possible to tell whether the abscess was deep in the abdominal wall or superficially located in the peritoneal cavity. In any case, all definite intra-abdominal masses resolved spontaneously without surgical intervention.

Infection of wounds. The administration of penicillin may cause a slight reduction in the incidence of wound infection, but it will not prevent it. Thirty-six per cent of the wounds became infected, but in no instance did a severe infection develop. The remarkable thing about the wound infections was the absence of severe local or systemic reaction. Often they behaved like cold abscesses, pointed, became fluctuant, and discharged spontaneously without making themselves evident by pain, a significant febrile reaction, or redness or tenderness of the tissues surrounding the wound. In no instance was there extensive cellulitis. Provided no deep sinuses were present, the wounds healed with remarkable rapidity after the discharge of the pus.

Side effects of penicillin. Approximately 100 patients treated with 100,000 units of peni-

Fig. 6. Diffuse pelvic peritonitis due to perforation in carcinoma of sigmoid. Penicillin instilled in peritoneal cavity and given parenterally. Death by pulmonary embolism on third postoperative day. Autopsy showed no peritonitis.

cillin every 2 hours for varying lengths of time had no serious side effects. Urticaria is the most distressing symptom, but it is rare and seems to occur no more frequently with large than with small doses.

Fever may occur and it is characterized by elevation of the temperature without a corresponding elevation of the pulse rate or increase in the clinical manifestations of the disease (Fig. 4).

SUMMARY OF CLINICAL COURSE

The clinical course of peritonitis of appendiceal origin treated by large doses of penicillin given over a long period of time can be summarized as follows:

1st and 2nd day. No apparent change in the general condition of the patient. Peritonitis does not appear to spread.

3rd day. Improvement in patient's clinical condition; pulse and temperature are lower; patient feels better; ileus subsiding; abdomen less rigid and tender.

4th day. If the patient is not definitely improved it is likely that mechanical small intestinal obstruc-

Fig. 7. Severe peritonitis. No operation.

tion is present. Roentgenogram of the abdomen should be made.

5th and 6th day. If there is no obstruction, patient is usually feeling well, eating a soft diet, and is alert and comfortable.

7th day. Occasionally intra-abdominal masses persist, but there is little fever and no symptoms.

8th to 12th day. If penicillin has been discontinued, signs of recrudescence of infection in abdominal abscesses should be looked for. A low-grade fever may be disregarded, but if it rises higher daily, or is accompanied by increasing pain, tenderness, or "gas pains," a second course of penicillin should be given.

Although this summary characterizes the course of the average case, an occasional resistant case will be encountered. If this occurs, one should not be discouraged but should continue treatment for 8 to 10 days. Eventually a response is usually obtained (Fig. 5).

Results of treatment of peritonitis with penicillin. In all of the 50 cases of proved peritonitis of appendiceal origin reported in this series the peritonitis has been controlled by the administration of penicillin. No intra-abdominal abscesses have drained spontaneously into the bowel or have required surgical

Fig. 8. Diffuse peritonitis. No operation. Large pelvic mass gradually absorbed without discharge of pus.

drainage. All intra-abdominal masses have eventually resolved, although several have required two or three courses of treatment. There have been no deaths as a direct result of peritonitis. The 1 death that occurred was due to thrombosis of the mesenteric veins, an indirect result of peritonitis which at the time of death was well controlled.

CASE REPORT

The patient was a young man who entered the hospital with a history of abdominal pain of 12 hours' duration. Abdomen was rigid enough to suggest the diagnosis of a perforated ulcer. Operation was performed immediately and what appeared to be a generalized purulent peritonitis was found. A culture showed *Bacillus proteus* and *Escherichia coli*. The appendix was perforated near its base.

Convalescence was uneventful for 3 days. The temperature fluctuated between 100 and 102, and the pulse rate remained elevated. On the third postoperative day the patient appeared a little better and the abdomen was somewhat softer. Later in the day his pulse became rapid and within a few hours it was imperceptible. The patient became delirious, then comatose, and despite supportive therapy, expired.

Postmortem examination revealed the general peritoneal cavity to be clean and glistening. An abscess approximately 1 inch in diameter containing thick white pus was present in the right iliac fossa

and a similar one was in the left. In the pelvis was another encapsulated abscess about a inches in diameter. The remainder of the peritoneal cavity was filled with an enormous amount of clear, blood-stained fluid, and the lumen of the small bowel was filled with this same material. Further examination revealed a diffuse thrombosis of the smaller mesenteric vessels. The remainder of the examination showed nothing remarkable.

This patient unquestionably died as the indirect result of peritonitis, but the localized and completely walled-off abscesses were not sufficient to have caused his death had he not developed a thrombosis of the mesenteric veins. This was the only fatality from appendicitis among the 900 patients operated upon in the past year.

Peritonitis secondary to perforating lesions of the large bowel appears to respond as readily to penicillin as does that due to appendicitis, provided of course that the contamination of the peritoneal cavity is controlled by exteriorizing or resecting the involved segment. Three patients with perforated carcinomas of the colon and one with a perforated diverticulitis of the colon have been operated upon and the involved bowel resected. In all cases from 12 to 36 hours had elapsed since the perforation and a diffuse purulent peritonitis was present. Yet in all cases the peritonitis was controlled. One patient expired as the result of a massive pulmonary embolism on the third postoperative day. A carcinoma of the sigmoid had perforated nearly 36 hours before. The pelvis contained several hundred centimeters of thick pus and the entire abdomen was rigid and gave

Fig. 9. Mass in right lower quadrant. No operation.

the appearance of a generalized peritonitis. The carcinoma was resected, the pus was aspirated from the pelvis, and 200,000 units of penicillin was placed in the peritoneal cavity. Two hundred thousand units were given intravenously and 100,000 units every 2 hours. On the third postoperative day, the temperature was between 99 and 100.5, the pulse between 100 and 130, and the abdomen was soft, flat, and not tender. The patient expired suddenly. Autopsy showed a massive pulmonary embolism, but aside from a little redness of the peritoneum, there was no evidence of peritonitis and no pus or fluid was present (Fig. 6).

In this series, the results of the management of appendiceal peritonitis have been much the same whether immediate operation was performed or whether the peritonitis was managed conservatively. In each case the average length of time before the temperature fell to normal was 8 days. Masses were palpable more frequently in the patients whose appendices were not removed. Mechanical intestinal obstruction, associated with the masses, occurred more frequently in the group not operated upon.

In the group operated upon, on the other hand, the patients appeared somewhat sicker, and experienced a more profound toxic reaction from the peritonitis.

Fig. 10. Abdomen explored. Abscess found but not disturbed. Appendix not removed.

The only death that occurred was in the operated upon group. Since intestinal obstruction of inflammatory origin is easily corrected by decompression with a Miller-Abbott tube, and since little can be done to combat the overwhelming toxemia incident to operation performed in the face of a fulminating peritonitis, it is my impression that conservative treatment is the safer method of dealing with seriously ill patients. In most cases, and especially when the general condition of the patient is good and sufficient penicillin is given to control the peritonitis, there is little to choose between the two methods of treatment (Figs. 7 to 12).

EVALUATION OF STUDY

There is strong evidence that peritonitis of appendiceal origin in both man and dog can be controlled by large doses of penicillin given over a long period of time. There is also evidence that penicillin levels of the blood are proportional to the amounts given intramuscularly and that the drug is present in ascitic fluid in about the same concentration as in the blood. Yet penicillin in concentration up to 20 units per centimeter does not inhibit the growth of *Escherichia coli* (1). *Escherichia coli* and other penicillin resistant organisms are almost always found in the cultures taken from patients with appendiceal peritonitis.

Fig. 11. Appendiceal abscess drained but appendix not removed.

How can it be explained that peritonitis due to mixed infections is controlled by concentrations of penicillin less than $1/10$ of the minimum level required to inhibit the growth of *Escherichia coli*, the predominant organism in the infection? And why is it that whereas in most infections the results of chemotherapy are prompt and dramatic, manifesting themselves within 24 hours of the initiation of treatment, in the treatment of peritonitis the results become apparent slowly? And, finally, why is it that four or five times the usual effective dose of penicillin is required to obtain a satisfactory result?

These questions can best be answered in the light of Altemeier's studies. Altemeier has shown that cultures of *Escherichia coli* or of *Bacillus pyocyaneus* have the property of destroying the activity of penicillin. If a known amount of penicillin is incubated with a culture of *Escherichia coli*, 98 per cent of the activity of the penicillin is destroyed in 12 hours.

This ability of *Escherichia coli* to destroy the activity of penicillin could well account for the fact that large doses of penicillin are required to control the gram positive cocci when they are growing in a mixed infection and are

Fig. 12. Appendiceal abscess ruptured at operation. Appendix removed.

associated with *Escherichia coli*. It also explains why it takes several days and large amounts of penicillin to control infections due to a mixture of *Escherichia coli* and gram positive cocci. By giving enough penicillin over a long period of time eventually more penicillin is given than the *Escherichia coli* can destroy, and finally there is built up a sufficient concentration of active penicillin to inhibit the growth of the virulent cocci.

Although it can now be seen how it is possible for large doses of penicillin given over a long period of time to inhibit the gram positive cocci, there is still no explanation as to why penicillin, in concentrations insufficient to inhibit *Escherichia coli*, eventually results in control of infections in which this organism predominates. It is possible that *Escherichia coli*, in pure culture, is not a pathogenic organism, but is in reality a mere saprophyte. If this were the case one need not rely on chemotherapy to control it, as the normal defense mechanisms of the body would be able to deal with it once the gram positive cocci were inhibited. The absence of cellulitis around the

Fig. 13. Acute appendicitis. Patient received 100,000 units of penicillin every 2 hours for 1 day. Penicillin then discontinued and within 5 days there was recurrence of signs and symptoms of localized peritonitis. Second course of penicillin then given over a period of 12 days. Temperature again fell to normal and signs of peritonitis disappeared. Ten days after patient had become afebrile, operation was performed and abscess containing several ounces of foul pus with *Escherichia coli* odor was found. Since systemic reaction had subsided and the mass was steadily decreasing in size, it is probable that this mass would have been absorbed spontaneously without surgical drainage.

infected wounds of patients receiving large doses of penicillin, the absence of tenderness of large intra-abdominal masses, the absence of friability of the tissues overlying these masses, the absence of paralytic ileus in the face of diffuse peritonitis when adequate doses of penicillin have been given for a few days, all of these findings and the frequent observation that the temperature may be normal and the patient may feel well in the presence of a large intra-abdominal mass, point to the fact that it is not *Escherichia coli* but the gram positive cocci that are the chief offenders in peritonitis. If the cocci are controlled, the peritonitis is controlled and the marvelous defensive and absorptive mechanism of the peritoneum is able to take care of the saprophytic or weakly pathogenic *Escherichia coli* infection.

In wounds, the defensive and absorptive action of the peritoneum is not available and, moreover, there is suture material, strangulated tissue, serum, and blood, in which

Escherichia coli can grow. Even if it does not invade and cause a cellulitis, a wound infection of low virulence is apt to develop. Instead of being absorbed, as it might be in the peritoneal cavity, eventually it drains. This explains the persistence of a normal expectancy of wound infections despite treatment with penicillin.

In only 1 case in this series was an inflammatory mass opened while it was still palpable. This patient had had 100,000 units of penicillin for 6 days and had been afebrile for 11 days. He had no symptoms, but a mass was still palpable. An interval appendectomy was advised and at operation, 4 or 5 ounces of foul, fecal-smelling pus was obtained and the general peritoneal cavity was extensively contaminated. Yet there was little systemic reaction and the temperature did not rise over 100. Unfortunately, no culture was taken, but despite the fact that *Escherichia coli* must once have been present to produce

Units of penicillin per c. c. of medium.		10	5	2.5	1.25	0.625	0.312	0.156	0.078	0.039	0.019	0.0097	0
Pure culture <i>Staphylococcus aureus</i>		—	—	—	—	—	—	—	—	—	+++	+++	+++
Mixed culture	<i>Staphylococcus aureus</i>	—	—	—	—	—	—	+	+	++	++	+++	+++
	<i>Escherichia coli</i>	+++	+++	+++	+++	+++	+++	+++	+++	++	++	+	+

the odor, the patient had no systemic reaction and the mass was becoming smaller each day and probably would have resolved spontaneously (Fig. 13). If sufficient penicillin is given to destroy the gram positive cocci, it would appear that the peritoneum can take care of the rest.

SUMMARY AND CONCLUSIONS

1. A group of 50 patients with proved appendiceal peritonitis treated by the administration of 100,000 units of penicillin every 2 hours for several days is reported.

2. There was but 1 death in this series and this did not occur as the direct result of peritonitis but from thrombosis of the mesenteric vessels.

3. In all cases of spreading peritonitis, the infection was controlled by penicillin.

4. In all cases of localized peritonitis with or without formation of a mass, the infection was controlled and the mass eventually was absorbed.

5. In no case was it necessary to drain an intra-abdominal abscess and so far as is known, there was no spontaneous drainage into the bowel.

6. It is suggested that the mechanism of action of large doses of penicillin in mixed infections is against the virulent gram positive cocci. *Escherichia coli* is known to inactivate penicillin, hence large doses of penicillin must be given for long periods of time if effective action against the cocci is to be obtained.

7. It is further suggested that *Escherichia coli* in pure culture usually is of low virulence and that if the virulent gram positive cocci are controlled by chemotherapy, the peritoneum is able to localize and eventually absorb infections due to the remaining *Escherichia coli*.

NOTE.—To check the *in vitro* resistance of mixed cultures to penicillin, a heavily seeded 18 hour agar slant of staphylococci Strain N.R. RL 209 was washed with a 6 hour broth culture of *Escherichia coli*. This was diluted to make a faintly turbid suspension and 0 or cubic centimeter of this was used as the inoculum.

After 24 hours' incubation at 37 degrees smears were made of all tubes and stained by Gram's method (setable).

It is apparent that concentrations of penicillin of 0.039 unit per cubic centimeter inhibited the staphylococcus in pure culture, but that concentrations of 0.372 unit per cubic centimeter were required to inhibit the staphylococcus in the presence of *Escherichia coli*. The bacteriology was conducted by Mr. Alfred Reich of the Cleveland Clinic.

The above figures indicate that approximately 8 times as much penicillin is required to control staphylococci in mixed culture without *Escherichia coli* as when the staphylococcus is in pure culture. This figure corresponds quite accurately with the increased dosage required to control mixed infections as compared with infections caused by gram positive cocci in pure culture.

TORSION OF THE SPERMATIC CORD

LEANDER W. RIBA, F.A.C.S., M.D., Lieutenant Colonel, M.C., A.U.S., Chicago, Illinois,
CARL J. SCHMIDLAPP, F.A.C.S., M.D., Captain, M.C., Cincinnati, Ohio

TORSION of the spermatic cord has been discussed and reported in the medical literature since 1840. Delasiauve described the first clinic case. In May, 1944, Ewert and Hoffman stated that the literature including June, 1943, revealed 489 cases of spermatic cord torsion. Many cases of torsion diagnosed at operation are never reported. Many cases in which operation is not done remain undiagnosed and the result is aseptic necrosis and late atrophy. The literature indicates that this urological emergency is still not recognized sufficiently early to save many of these testes by surgical intervention. In 80 reported cases 64 (80 per cent) had been operated upon and in only 15 (23.5 per cent) could the testis be saved by detorsion. In 49, or 76.5 per cent, of the cases orchietomy had to be performed for testicular aseptic necrosis. The remaining 16 (20 per cent) cases showed that 5 had spontaneously reduced themselves; in 3 the detorsion was accomplished by the patient; in 5 immediate surgery was refused and later follow-up showed complete atrophy; in 3 others the diagnosis of torsion can well be questioned.

ETIOLOGY

A great deal has been written about the etiology of torsion, but some factors still remain obscure. In the absence of trauma there exists a congenital anomaly which predisposes to acute or recurrent torsion. Torsion of the spermatic chord may occur outside of the tunica vaginalis (extravaginal) or inside of the tunica vaginalis (intravaginal). Extravaginal torsion occurs more readily in undescended testes in the presence of trauma and is much less common. Lowsley and others deny the occurrence of extravaginal torsion and accept the only case reported by Taylor in 1897. The intravaginal type of torsion is most common

and may occur in undescended and descended testes alike. Existing anomalies predisposing to intravaginal torsion are: imperfect descent, absent or long mesorchium, absent or long gubernaculum, high investment of the tunica vaginalis, intravaginal insertion of cremasteric muscle, and redundant scrotum. In addition, the vascular pedicle does not enter the testis through the body but rather through the upper pole. With such an anomalous "cherry stem" vascular pedicle, an absent mesorchium and high investment of the tunica, we have a perfectanlage for intravaginal torsion of the spermatic cord. Muschat has demonstrated cremasteric fibers inside of the tunica vaginalis which he believes under the right conditions are responsible for torsion. Indirect muscular exertion and trauma frequently precede torsion. There are other cases, however, such as those occurring during sleep, in which the exciting factor still remains obscure. The scrotal structure which precipitates torsion is the contraction or segmental contraction of the cremasteric muscle.

This condition may occur at any age; Hegner and Postma and Langley reported inguinal torsion in 4 months old infants and O'Connor reported one in a man 68. The majority occur before the 20th year. O'Connor in 124 cases found the average 13.3 years, and Abeshouse in 350 cases the average age 17.7 years. Clute states that 47 per cent occur between the ages of 15 and 25. Ewert and Abeshouse report that the right and left sides are equally involved. Twenty-six cases of bilateral spermatic cord torsions have been recorded. Scudder reported that about one-half (47 per cent) occur in undescended testes.

SYMPTOMS

The history of acute excruciating pain in the testis of a patient who has unassociated urinary tract infection should lead us to suspect an acute torsion of the cord. While the

From the Surgical Branch, Urologic Subsection, Bushnell General Hospital, Brigham City, Utah.

acute pain may follow any type of muscular effort or exertion, it can awaken a patient out of a sound sleep. Patients may become nauseated, vomit, and observe rather soon a sudden swelling of the involved testicle. The pain may be most severe during the first 24 hours and after 48 to 72 hours it will spontaneously begin to subside. When the testis is in the groin or within the abdomen the corresponding thigh may be held in the semiflexed position. In the presence of urinary tract infection or gonorrhea, the diagnosis of acute torsion becomes exceedingly difficult.

Before the age of 20, a history of recurrent pain in one or both testes, in the absence of infection, should lead us to suspect chronic recurrent torsion in every patient.

PHYSICAL FINDINGS

The physical findings in the acute and chronic cases are quite dissimilar. In acute cases there is an early swelling, edema, and tenderness involving the affected scrotal sac. Prehn in 1937 noted in acute epididymitis that elevation of the testis would tend to relieve the pain while in acute torsion the pain was always aggravated (Prehn's sign.) Also Ownby and Atkinson in 1942 emphasized the early edema and fixation of the scrotal contents to the adjacent coverings. They stated that when present Dr. James Dillon had repeatedly called their attention to this valuable diagnostic aid (Dillon's sign.) Often the testicle will be elevated but due to the edema it is impossible to differentiate the testicle from the epididymis. The cord above the testicle is usually enlarged. In the absence of infection there are usually no additional urologic abnormal physical findings. The white blood count may be elevated even as high as 20,000. The pulse and temperature usually are normal. In neglected cases of spermatic cord torsion there may be still some enlargement but the outstanding findings are the rubbery, firm, smooth, testicular consistency with elevation and retraction of the testis against the external inguinal ring (Fig. 1). In late cases the testes become smaller and asymptomatic, finally ending in complete atrophy. The epididymis is usually involved and causes the irregularities noted on palpation.

DIAGNOSIS

The diagnosis in many instances should be suspected from the history. Many patients give a history of recurrent testicular pain and swelling. The findings of acute swelling following sudden pain in the testis and with all other examinations negative, strongly suggest torsion of the spermatic cord. It is usually impossible to differentiate between the epididymis and testicle in acute cases. When present Prehn's and Dillon's signs may be helpful. It is of extreme importance to make an early diagnosis if the testicle is to be saved.

DIFFERENTIAL DIAGNOSIS

Acute epididymitis. Acute epididymitis in many ways may so simulate acute torsion that a differential diagnosis becomes extremely difficult. In the presence of urethral discharge, pyuria, prostatovesiculitis or a recent history of neisserian infection, acute epididymitis would seem more likely. With acute vasitis and funiculitis, palpation of the inguinal cord will reveal more tenderness than is found in most cases of torsion. Prehn's sign should be negative in epididymitis. McKay reported an acute torsion in the presence of a positive smear. A patient with acute epididymitis usually runs some fever with a moderate elevation of the white blood count.

Strangulated hernia. The symptomatology of acute strangulated hernia may be very similar to acute torsion of an inguinal testicle. The pain may be identical but the gastrointestinal symptoms will be less severe in torsion. Painful inguinal masses and swellings occurring in patients with undescended testes should make us suspect acute torsion. While the differential diagnosis may be most difficult in some cases, early surgical exploration is indicated in either case.

Torsion of the appendix testis. Torsion of the appendix testis occurs when this embryonal rest is pedunculated and becomes strangulated. Sudden severe pain may occur, but usually there is less swelling, edema, or testicular fixation. Palpation will reveal localized exquisite tenderness over the strangulated appendix testis.

Acute orchitis. Acute orchitis may follow or precede mumps or complicate a surgical

Fig 2. Case 2. The remaining testis in recurrent bilateral torsion is sutured with interrupted silk to the dependent serotal fascia.

vascular constriction. In a patient in whom the artery as well as the vein has been suddenly occluded, the viability will be shorter than if only the vein is primarily occluded. While manual detorsion is always possible without surgery, the technique is unsafe and should be discarded. Surgical detorsion should always be followed by orchidopexy to preclude subsequent attacks. Ormond's case of a physician who practices manual detorsion for 12 years without testicular atrophy is an exception rather than the rule. Apparently this was recurrent partial venous occlusion which could be satisfactorily reduced. Cahen operated upon a patient 12 hours after occlusion, found testicular gangrene necessitating orchidectomy. The practice of applying hot formication after detorsion is a good index of testicular viability. Surgical intervention within 12 hours will save the majority of acute torsions, but Birdsall states "in the majority of cases in which the diagnosis has been made early and the testicle found to be viable and detorsion performed, the testicle has undergone atrophy." Occasionally the strangulated tissue becomes infected resulting in gangrene.

In chronic recurrent cases the simple fixation of the lower pole of the testis to the dependent tunica vaginalis (Fig. 2) and fasciae will obviate subsequent acute attacks and gangrene. In all bilateral cases, the mate should be treated by fixation. Campbell has used the Jaboulay operation for the fixation of the opposite testis. In this technique the tunica vaginalis is everted to prevent a hydrocele, and the testis is anchored to the scrotum.

CASE REPORTS

CASE 1. R.B., aged 20 years, while home on an overseas furlough on April 9, 1943, was suddenly seized during sleep with severe pain in the left testis.

testicle with re...
ends upon the amount

Fig. 3. Case 1. R.B., aged 20 years, shows $1\frac{1}{2}$ clockwise turns to left producing aseptic gangrene of the testis. This patient went through several Southwest Pacific campaigns but not until he arrived home on an overseas furlough did he experience an acute torsion of the spermatic cord.

Within 2 hours the testis began to swell and a local physician was called. He admitted several recent sex exposures but denied any evidence of urethral discharge or history of venereal disease. A diagnosis of gonorrheal epididymitis was made and he was treated unsuccessfully with oral sulfonamides. On admission to Bushnell on May 9, 1945, examination revealed a slightly enlarged, firm, left testis and epididymis. The testis compared to the right seemed somewhat fixed within the upper scrotum. The remainder of the physical examination, x-rays, and laboratory tests were negative and noncontributory. A diagnosis of suppurative epididymitis was made and exploration on May 19, 1945, revealed marked peritesticular adhesions making delivery difficult. The mobilized testis was firm and irregular. The tunica vaginalis was opened and an intravaginal twist of $1\frac{1}{2}$ clockwise turns was noted at the upper pole (Fig. 3). The tunica vaginalis was pale, fibrous, and slightly adherent to the tunica albuginea. Incision of the testis revealed testicular necrosis and a hemorrhagic distended epididymis. There was no bleeding. Removal of the cord and testis was carried out. The pathologic report showed aseptic necrosis and hemorrhage involving the entire testis and epididymis (Fig. 4). Following recovery patient was returned to duty.

It is interesting that this patient was fortunate to go through many front line battles unscathed and while at home in bed on an overseas furlough he suffered an acute undiagnosed lesion resulting in loss of one testis.

Fig. 4. Case 1. Microscopic section, torsion of the spermatic cord showing chronic inflammation, fibrosis, and an old hemorrhage into the tunica and superficial portion of the testis. Acute infarction of the testicular substance

CASE 2. C.M., aged 22 years, gave a history of testicular injury at the age of 8 years. For the past 14 years he has had recurrent attacks of pain in each testicle, each attack lasting for 1 to 4 days. At 9:30 a.m. on July 1, 1943, he developed acute pain in the left testis. Later he developed pain in the left abdomen and swelling of the testicle. He was admitted to the station hospital and given morphine for persistent pain. After 4 weeks of symptomatic treatment he was transferred and admitted to Bushnell on July 28, 1943, with a diagnosis of orchitis. Examination revealed the right testis and epididymis to be normal. The left was enlarged $1\frac{1}{2}$ times, hard, smooth, but not tender. There was slight enlargement of the left vas deferens and a small palpable nodule over the left pubic bone. The prostate and seminal vesicles were normal. The abdomen revealed no abnormalities, but was sensitive to deep palpation in the left lower quadrant. X-ray studies of the urinary tract, chest, and scrotum revealed no abnormalities. The blood count, urinalysis, and serology were within normal limits. The prolan A test of the morning specimen of urine was negative. Diagnoses of chronic torsion of the left spermatic cord with necrosis and chronic right recurrent torsion of the right spermatic cord were made. On August 11, 1943, under spinal anesthesia, the left testicle was delivered through a low left inguinal incision. Marked fibrous adhesions were noted surrounding the testicular coverings. The tunica vaginalis was yellowish-green and adherent to the tunica albuginea (Fig. 5). Upon dissection it was noted that the superior pole of the testicle presented a small, twisted, avascular pedicle with $1\frac{1}{2}$ clockwise turns. The testicle was incised and there was no bleeding. The parenchyma was soft, putty-like, with a brown color. The left inguinal cord and testis were removed. The most dependent portion of the right scrotal sac was incised so as to include the tunica vaginalis. The exposed albuginea was sutured to the vaginalis and scrotal fascia with interrupted black silk (Fig. 2). Both incisions were closed with silk without drainage. The patient made an uneventful recovery and was returned to full military duty.

Case of bilateral chronic recurrent torsion for 14 years which finally resulted in the loss of one testis. Bilateral orchidopexy should have been carried out many years before.

CASE 3. J.J., aged 23 years, 2 hours following sexual intercourse with an Alaskan Eskimo developed severe pain and swelling of the right testicle. In the hospital he was treated for acute epididymitis with oral sulfonamides. The swelling and soreness subsided after 18 days, but some induration remained. He remained well for $1\frac{1}{2}$ years and in December, 1943, the tenderness and swelling recurred. He was again treated in the hospital for acute epididymitis. After 26 days, the swelling again subsided, but the right testis remained firmer than

Fig. 5. Case 2 C.M., aged 22 years, aseptic necrosis of the left testis 6 weeks after acute torsion showing avascular dark brown putty-like testicular parenchyma.

the left. He was returned to the continental United States with a diagnosis of neoplasm. On April 10, 1944, he was transferred to Bushnell. Examination of the urinary tract was entirely negative and the findings were limited to the scrotum. The right testis was smaller than its fellow and appeared rubbery hard and retracted into the external ring (Fig. 1). The left testis and epididymis were normal. The prostate and its secretion were normal, the urine was grossly clear. Laboratory examination of the urine, blood, and serology revealed no abnormalities. The prolan A test of the morning urine was negative. Preoperative diagnosis of chronic torsion of the right spermatic cord was made. On April 14, 1944 under local anesthesia, the right inguinal cord and upper scrotum were exposed. The testicular coverings were markedly adherent making delivery of the testis difficult. The testicle was small and rubbery in consistency with a firm area on the superior anterior pole representing the epididymis. The tunica vaginalis was very adherent and thin. Incision of the tunica albuginea revealed a greenish appearing testicle with a "cherry stem-like" pedicle. The pedicle above the upper pole had one complete counter-clockwise turn, occluding the testicular blood supply. The cord was doubly clamped, ligated, and removed with the testis. Pathological examination showed a torsion of the spermatic cord with chronic inflamma-

Fig. 6 Case 3. Four months after acute torsion of the right spermatic cord the testis was small and on section showed an avascular greenish appearing parenchyma with a "cherry stem-like" pedicle.

tion and infarction of the right testicle and epididymis. Patient was returned to duty.

The sudden onset of acute testicular pain 2 hours following intercourse, in the absence of infection, should have suggested an acute torsion and immediate surgery.

CASE 4. M.J., aged 22 years, in October, 1944, received a gunshot wound injuring the spinal cord at the level of sixth dorsal vertebra, resulting in immediate paralysis below that level. He received symptomatic treatment, and tidal drainage was begun with an indwelling urethral catheter. He was admitted to Bushnell on January 2, 1945, with a diagnosis of transverse myelitis, resulting in complete bowel, bladder, and leg paralysis. This patient was seen by the urologic service the first time on the day of admission and a well functioning urethral catheter was noted. The urine was cloudy and the original cultures showed diphtheroids, proteus, and Gram positive cocci unidentified. The cystometrograph made on February 2, 1945, showed a capacity of 450 cubic centimeters and a maximum voluntary pressure of 86 centimeters of water. On March 30, 1945, many bladder concretions were removed through a panendoscopic sheath. On May 26, 1945, he was seen again on account of swelling of the left scrotal sac. The left scrotal sac was red, swollen, but only slightly tender. The left vas deferens seemed indurated above the swelling. The indwelling catheter and tidal drainage were working well. Acute nonvenereal epididymitis was diagnosed and sulfadiazine, 1 gram four times daily, and penicillin 25,000 units, every 3 hours were initiated. This treatment was continued for 15 days without noticeable improvement. On June 13, 1945, an exploration of the left scrotal contents was carried out under intravenous pentothal anesthesia. The testis was delivered with difficulty due to fibrous adhesions involv-

ing all the structures around the left testicle. With sharp dissection, the testis was delivered and opening of the tunica vaginalis showed aseptic necrosis. The vascular pedicle was anomalous, twisted 3/4 clockwise turn and attached to the upper pole of the testis. The entire mass including the left spermatic cord was removed. The microscopic sections showed old and recent thrombi involving arteries and veins of the spermatic cord with aseptic necrosis of the left testis and epididymis. The wound healed *per primam*. The right testicle has remained normal.

This patient has a complete paraplegia, but contractions of the cremasteric muscle are preserved and occur while the patient has "abdominal spasms." This is the first recorded case of torsion occurring in a total paraplegia and suggests segmental cremasteric contractions. Acute torsion was not considered in the differential diagnosis on the first visit.

CASE 5. H.B., Negro, aged 20 years, had swelling and pain in the left scrotal sac in 1941 which lasted for 1 day. He had a similar attack in 1942 while walking to work. An attack of acute gonorrhea in 1943 was cleared in 2 weeks without complications. While lying down on an island overseas on May 29, 1945, he experienced an acute excruciating pain in the left scrotal sac followed by swelling. He was admitted to the station hospital and treatment for acute epididymitis was begun. He failed to improve and was transferred to Hawaii and admitted to the 318th General Hospital on June 8, 1945. Admission examination revealed the left testis three times the size of the right, smooth, firm, and what seemed to be an indurated epididymis. The skin overlying the left scrotal contents was definitely adherent anteriorly. Intravenous pyelograms and chest film were normal. The urine was clear and negative for tubercle bacilli. The tuberculin skin test showed 1+ positive. The administration of 200,000 units of penicillin failed to reduce the swelling. Chronic torsion was now suspected. On July 5, 1945, exploration of the left scrotal contents revealed marked peritesticular adhesions, intravaginal torsion 3/4 counterclockwise turn, "cherry stem" vascular pedicle and yellow-green tunicae. Incision of the testis showed no bleeding. The testicle and cord were removed. The microscopic sections showed complete aseptic necrosis of the testicle and epididymis due to spermatic cord torsion. Following the operative recovery was uneventful.

Acute torsion occurring in a soldier under fire resulting in an improper immediate diagnosis, neglect, and loss of one testicle. The correct diagnosis should have been suspected from the history (C.J.S.).

SUMMARY

An anomaly of the testicular attachments and the vascular pedicle is necessary for torsion of the cord to take place. The precipitating factors are the intravaginal and extravaginal fibers of the cremasteric muscle. Muschat has shown that, when the tunica vaginalis abnormally invests and encircles the entire epididymis, the testis and epididymis will not be attached to the scrotal wall. In these cases the testicular blood supply enters the upper pole. A polar pedicle with a high investment and a relaxed tunica is an ideal anomaly for an acute torsion. Why and how the contractions of the cremasteric muscles are initiated is still not well understood. It is understandable how muscular effort, direct or indirect, may influence its contractions but it is less understandable when torsion occurs during periods of physical relaxation or sleep.

It is of unusual interest to note the case of acute torsion in complete transverse myelitis (Case 4). Segmental cremasteric muscle contractions of the lateral and median fibers may be observed in this patient's scrotum. In the presence of an anomalous testicular pedicle unco-ordinated segmental spasms and contractions of the cremasteric muscles could readily precipitate and maintain an acute spermatic cord torsion until tissue edema and swelling supervene. Goodrich suggested the counterspin of the testis was an important factor in acute torsion. This seems, in part, to be the *modus operandi*, as only a few cases undergo spontaneous detorsion. In cases of mild recurrent torsion there is only sufficient testicular mobility to cause passive congestion and pain. These mild cases may reduce themselves or are reduced by the patient.

The record in the management of spermatic cord torsion leaves much to be desired. The early signs and symptoms are still unrecognized and ignored. Masterly inaction instead of immediate surgery still results in the loss of 75 per cent of the testicles in patients operated upon late. If in the differential diagnosis of every inguinal and scrotal swelling characterized by severe sudden pain, torsion were considered, many more cases would be diagnosed early. The history itself many times suggests the correct diagnosis. Acute testicu-

lar pain following any conceivable type of muscular exertion, work or play, should forever raise the question of torsion in the examiner's mind. Torsion occurring during sleep should be more widely recognized and followed by prompt surgical exploration. In all fairness, the fault is not always on the side of medical attendants. Parents and patients refuse early surgery in approximately 15 per cent of cases.

Many testicles could be saved if we would explore a few cases of acute epididymitis for a mistaken torsion rather than treat the majority of acute torsions conservatively as epididymitis. Acute epididymitis treated surgically usually recovers while torsion treated by inaction and conservatism will result in fibrosis and complete testicular atrophy.

CONCLUSIONS

1. Acute torsion of the spermatic cord is frequently undiagnosed, and after its occurrence only 1 in 5 testes are saved.
2. Intravaginal torsion in descended testicle occurs when an anomaly of the testicular attachments and pedicle is present, precipitated by segmental contraction of the cremasteric muscle.
3. Chronic torsions of the spermatic cord should be anchored surgically to the dependent scrotum before the acute emergency occurs.
4. Acute torsion operated upon immediately or within 8 hours will usually result in a viable organ.

EXPERIMENTAL STUDY ON LIVER FUNCTION TESTS

CARLOS A. TANTURI, JUAN F. CANEPA, RICARDO BAY, and ROBERTO F. BANFI,
Buenos Aires, Argentina

THERE is at present a tendency to perform simultaneously several tests of liver function and to repeat them during the course of an illness since this is the only way of obtaining fairly accurate data concerning the functional state of the organ. This tendency, perfectly justified by the studies of experimental hepatic pathology and recently confirmed by studies with patients (24, 25, 26, 28, 30, 35), is based on the following facts:

1. The liver is characterized by its multiple functional activities and these may be variously affected by a certain type of lesion. Thus "the employment of a number of tests in different phases of the disease will lead to a satisfactory appraisal of the physiologic status of the organ" (23).

2. "The hepatic function varies not only from day to day but from hour to hour" (Ivy). In this statement are implied the concepts of duration of illness and of hepatic regeneration. The time element (duration of illness) is important as regards hepatic regeneration. The liver's great capacity for regeneration is a factor that limits the use of liver function tests. "Unless the hepatic injury be extensive and rapid the simultaneous incidence of regenerative processes can compensate and overshadow the destructive effect of the pathological processes" (21). We were able to confirm this assertion (4, 5).

3. A close interrelation exists among the intrahepatic and extrahepatic (biliary tract) pathological processes. Snell and Magath pointed out accurately that clinically a gross extrahepatic biliary obstruction does not exist without injury of the hepatic parenchyma, nor a pure form of jaundice without injury or obstruction of the finer bile ducts or canaliculi. This fact must be taken into account when the purpose of liver function tests is that of ob-

taining data for the differential diagnosis of jaundice.

As Ivy (21) has pointed out, the purposes of performing liver function tests can be summarized in three main objectives: (a) to establish whether or not a hepatic disturbance exists, (b) to establish a prognosis of the disturbance and to aid in determining the surgical risk, (c) to determine the differential diagnosis of jaundice.

Drill and Ivy (14) made a comparative experimental study of five liver function tests. They used dogs to which they administered twice a week small doses of carbontetrachloride, a hepatotoxic drug. The purpose of their study was to investigate the comparative sensitivity of the tests in three respects: (a) capacity to discover the hepatic damage, (b) continued validity of the tests as the administration of carbontetrachloride was prolonged, and as well (c) the existence of association or dissociation among the several liver function tests.

With an almost similar purpose we, coincidentally and independently, have made a comparative experimental study of the prothrombin concentration of plasma, the bilirubinemia, and the acid and alkaline phosphatase activity of the serum of dogs in which different degrees of hepatic damage were produced: (a) by chloroform anesthesia, (b) by cholecystectomy and ligation of the common duct, and (c) by cholecystectomy. Cholecystectomy alone was chosen as a procedure that produces, in dogs, modifications of the phosphatasemia not attributable merely to a post-operative reaction but apparently due to a determined though slight degree of biliary insufficiency (12).

METHODS

1. *Chloroform anesthesia.* Normal dogs which had been fasted for 3 days (water at will) were used. They were subjected to a

From the Laboratory of Experimental Pathology and Surgery, University of Buenos Aires, Argentina.

Chart 1.

Chart 2.

according to the average of results obtained from normal dogs.

RESULTS

1. *Chloroform anesthesia.* From Table I and Charts 1 and 2 it can be seen that:

a. Increase in alkaline phosphatase and decrease in prothrombinemia are more sensitive indices than is bilirubinemia in detecting the hepatic damage produced by chloroform anesthesia.

b. Hypoprothrombinemia is an earlier index of hepatic damage than is hyperphosphatasemia. It reaches its maximum during the 24 to 48 hours following the anesthesia while the highest value of the phosphatasemia is recorded between 48 and 120 hours following the anesthesia.

c. At the 5th day (or at most, the 6th) the prothrombinemia has reverted to its normal value while the phosphatasemia remains above the normal level until the 10th to the 13th day.

d. The value of the bilirubinemia is not greatly modified, ascending slightly and reaching its maximum between 24 and 48 hours, and then reverting to normal. Compared with prothrombinemia, bilirubinemia gives no information regarding the severity of damage.

2. *Cholecystectomy and ligation of the common duct.* Tables II and III, and Charts 3, 4, and 5 show that:

a. The increase in serum alkaline phosphatase is greater than that in the experiments of chloroform intoxication (one hundred and fifty times the normal initial level). Fifteen hours after operation the increase is very pronounced, but the maximum value is reached at some point between the 4th and 94th day. Then an irregular and constant decline begins which lasts until the death of the animal. This decrease may reach a value smaller than the initial increase, but is always above the normal level.

b. The acid phosphatase activity parallels the alkaline but to a lesser extent. This increase is slightly greater than in the case of chloroform intoxication.

c. Bilirubin increases after the ligation of the common duct. The maximum concentration is obtained between the 4th and the 52d day following operation. Afterward it stabilizes at a level slightly above the normal. In one experiment (Dog 375, Chart 5) a sudden decrease to a 0 level can be observed. The autopsy findings revealed a spontaneous rupture of the biliary passages.

d. Prothrombinemia is late in revealing hepatic damage due to obstruction; only at the final period of the experiment is its value consistently low.

3. *Cholecystectomy.* Table IV shows:

a. The alkaline phosphatase increases in the cholecystectomized dogs; the increase is great-

SURGERY, GYNECOLOGY AND OBSTETRICS

Chart 3.

er than in the chloroform experiments but less than in experimental biliary obstruction. The maximum level is observed between the 10th and the 16th day following operation. After this period a decline begins and the normal level is reached at the end of the 50th day.

b. The bilirubinemia does not suffer any variation.

c. The prothrombinemia was not studied in these experiments since previous work done in this laboratory demonstrated that in cholecystomized dogs it changes only slightly during the first 24 hours following operation. This change is not due to the cholecystectomy itself since the same variations were observed

in dogs in which all the surgical steps, except the removal of the gall bladder, were repeated (3-6). The slight variations in the prothrombinemia do not last more than 24 hours and are attributed to the anesthesia and section of the tissues.

COMMENT

The alkaline phosphatase is present normally in the blood serum and its increase has been related to different types of liver injury (1, 2, 8, 9, 15, 18, 19, 29); therefore it was considered a sensitive indication of the hepatic damage (in absence of bone lesions). Several studies (9, 27) seem to indicate that the liver

Chart 4.

Chart 5.

is an important source of this enzyme. It is almost certain that the alkaline phosphatase excreted in the bile is of hepatic origin (15, 17).

Drill and associates (13) claim that the increase of the alkaline phosphatase activity of

serum accompanying the hepatic lesions is related to an alkaline phosphatase normally present in the blood in very small quantities and this might be the alkaline phosphatase II, which was extracted from the liver tissue by Cloetens.

Kabath obtained the release of the enzyme through cellular autolysis. Sharnoff, Lisa, and Riedel assert that the injured cells release phosphatase into the blood; consequently the degree of the injury regulates the enzyme level reached in the blood. Any agent able to produce necrosis or necrobiosis of the hepatic cells of the middle of the lobule (which contain phosphatase and apparently are the earlier

sufferers of the injuries) will produce an abnormal release of the enzyme into the blood. Transfusion of dog's icteric blood (which contains increased alkaline phosphatase) to a normal dog, increases the blood phosphatase of the recipient, and this increase persists a considerable time after the bile pigments are excreted (15).

Our experiments show that the highest levels of blood alkaline phosphatase are obtained following experimental extrahepatic biliary obstruction. In hepatitis due to chloroform an increase is found which persists even after the prothrombinemia has reached its normal level. This increased phosphatasemia, which lasts only a few days, can be explained by the slow excretion of the excess phosphatase released during the period of the maximum injury produced by chloroform (48 hours). The protein structure of phosphatase and the persistence of an alkaline phosphatasemia above the normal when the prothrombinemia has reached its normal level (chloroform hepatitis) might well be interpreted as an indication of a biliary obstruction or hepatic injury which is recovering. In other words, phosphatase is in the bile, once the enzyme reaches the blood either by cellular lysis or by

the bile pouring out into circulation the phosphatase can not be re-excreted through the biliary passages even if these have been completely restored. The experiment of the transfusion of icteric blood with increased phosphatase to a normal dog (15) referred to above warrants that conclusion. If this interpretation is correct, the determination of the alkaline phosphatasemia as a test of liver function would be submitted to a limitation which should be considered, especially if it is used as a single liver function test. In this latter case, the hyperphosphatasemia might denote a hepatic damage which had existed before. The doubt could only be cleared up by repeating the determination on succeeding days and by comparing the results with the results of other liver function tests. Even so, the comparative values will depend on the reliability of the tests chosen for the comparison.

In the work of Drill and Ivy (14) in studying the comparative sensitivity of tests, it was shown that the bromsulfalein test was the most sensitive in detecting hepatic damage. All the animals, except one, had hyperphosphatasemia at the same time or slightly after the bromsulfalein clearance had reached the normal values. Obviously the phosphatasemia was as sensitive as the bromsulfalein test. The prothrombin time was not so sensitive as the above mentioned tests, though it detected the hepatic damage prior to the galactose tolerance test.

In our experiments the prothrombinemia was the most sensitive test in detecting the hepatic injury produced by chloroform because it preceded the increase of the blood alkaline phosphatase. The results of Drill and Ivy are disputable concerning the prothrombin technique used by them. The difference in our results when compared with those of Drill and Ivy, cannot be accounted for by the different hepatotoxic drug used by us (chloroform) because it was demonstrated (3) that chloroform produces the same variations in prothrombinemia as does the carbon tetrachloride in similar experimental conditions. Our results show that prothrombinemia detects earlier than the phosphatasemia the hepatic damage produced by chloroform, and

its variations closely indicate the course of the injury as well as the reactive capacity of the liver. As has been said, phosphatasemia persisted at a high level even after prothrombinemia had reached its normal value and the high level was not the expression of a lesion in activity but in regression.

We have mentioned that the highest values of phosphatasemia are obtained in experimental extrahepatic biliary obstruction. It seems that phosphatasemia is a very sensitive index of biliary obstruction, either intrahepatic or extrahepatic, if the experimental results of ligation of the common duct and those of cholecystectomy are compared.

In extrahepatic biliary obstruction there are two factors to be considered: (a) the pouring off of bile (which contains the phosphatase secreted by the uninjured cells of the liver as well as other elements) into the blood stream; (b) the release of phosphatase directly into the blood by the injured cells. This explains the highest values of bilirubinemia and phosphatasemia found in this instance. The bile pigments are excreted through the kidneys, and this excretion accounts for the steady blood level that follows the initial increase (dogs 362 and 379) except when a rupture of the biliary tract (dog 375) suddenly dropped it to a 0 level. On the contrary the kidney is impermeable to phosphatase (17) and this persists at a high level in the blood nearly until the end of the experiment when the hepatic damage is severe and the hepatic insufficiency is at its height as is revealed by the marked hypoprothrombinemia. It is probable that at this moment the liver cells are deprived of phosphatase though its lysis does not increase the enzyme level in the blood (31).

In experimental biliary obstruction prothrombinemia is late in denoting the hepatic damage; only in the final period of the experiment is its value really low. These results confirm our earlier experiments (4) on experimental biliary obstruction in which it had been shown that prothrombinemia does not suffer significant variations (hemorrhagic levels) during the survival period of the animal, and that the hypoprothrombinemia and hemorrhagic tendency observed in the clinical cases of obstructive jaundice are due to the

injury of the hepatic cells, which complicates or follows the biliary obstruction, and is not due to the mechanical disturbance of the intrahepatic biliary stasis.

Special mention of the behavior of the acid phosphatase is necessary. In experimental biliary obstruction acid phosphatase does not vary in the same magnitude as does the alkaline; however, it increases and this increase is slightly higher than that observed in the chloroform experiments. In experimental biliary obstruction acid phosphatasemia parallels alkaline phosphatasemia variations although in a much smaller proportion. No explanation of this fact can be offered based on our present knowledge.

The results of the experiments of cholecystectomy revives the problem of cholecystectomy and dilatation of biliary ducts and hepatitis (7).

Cantarow (10) reported that cholecystectomy in man temporarily decreases the bromsulfalein excretion when the test is performed 24 hours following operation. Bergh (7) did not find functional hepatic changes in cholecystectomized dogs from 1 week to 15 months following operation; they used the bromsulfalein at a dose of 2 milligrams per kilogram of body weight, the van den Bergh reaction and the icterus index as liver function tests. As it was recently shown that the bromsulfalein test at a dose of 5 milligram per kilogram body weight is a more sensitive index, and that phosphatasemia is also a very sensitive index of the hepatic injury (14) Drill, Annegers and Ivy (12) restudied the effects of cholecystectomy on the hepatic function in dogs by means of both tests. Ten of 12 cholecystectomized dogs showed an increased phosphatasemia following the operation and in 9 of them this increase lasted as long as 70 days—the entire period of observation. Four of these 10 dogs showed an increased bromsulfalein retention. Drill, Annegers, and Ivy explain the hyperphosphatasemia observed following cholecystectomy in dogs on the basis of the experimental finding that cholecystectomy produces a dilatation of the bile ducts (7) and an incompetency of the sphincter of Oddi which permits transmission of the intraduodenal pressure into the biliary tract (20). They

were not surprised by the long lasting increased phosphatasemia after cholecystectomy though they considered it to be a sensitive index of the slight functional biliary obstruction connected with the dilatation of the intrahepatic bile ducts.

Our results confirm those of Drill (12) concerning the increase of the blood alkaline phosphatase following cholecystectomy in dogs. Although our studies were performed on only 2 dogs, the results closely coincide and warrant definite conclusions. However, in our animals the phosphatasemia returned to normal at an earlier period. This return to normal cannot be explained nor can the mechanism by which the functional changes of the intracanalicular pressure causes the phosphatasemia to rise.

The bilirubinemia does not change following cholecystectomy in dogs and this is not surprising if the great excretory capacity of the liver for bilirubin is recalled. Moreover, the increase of phosphatasemia is not necessarily associated with jaundice (15), and this is clearly shown in our cholecystectomy and chloroform experiments. These emphasize the concept of the existence of hepatic injuries which are not revealed by variations of the bilirubinemia.

Our comparative results show the existence of liver function tests which are very sensitive in their capacity to detect the hepatic damage, the course of the lesion, the reactive capacity of the liver, and the minimal biliary obstruction.

We have not attempted to evaluate the different tests as aids in determining the differential diagnosis of jaundice because, as is known, the dog is not an experimental subject for that purpose since he requires very extensive and severe hepatic damage or a total biliary obstruction to produce a degree of jaundice of certain intensity. However, this does not nullify the value of the results obtained from the comparative study of the bilirubinemia with the other tests.

In spite of the limitations imposed by the fact that it is not always possible to apply the results of animal experimentation to the human, our experiments demonstrate that: (1) prothrombinemia is more sensitive than

phosphatasemia in detecting cellular hepatic lesions, the course of the lesion, and the reactive capacity of the liver against injury; (2) phosphatasemia is more sensitive than is prothrombinemia in detecting the minimal biliary obstruction, i.e. one which could be designated as *functional biliary obstruction*. These statements apparently suggest the idea of the existence of a dissociation of the liver function tests which obviously implies the concept of a dissociation of the functions of the liver (metabolic and excretory). This is not erroneous so far as it is concerned with the reserve power of the liver. However, in accepting this idea one is forced to consider the existence of a systematized pathologic histology of the liver (pure forms of cellular injury and pure forms of canalicular injury) which, as is known, does not agree with the clinical reality.

The evidence points out that a given degree of hepatic injury does not equally affect the different functional activities of the liver in a quantitative manner, and, in order to gain knowledge of the course of any kind of hepatic damage, it is necessary to perform a series of different liver function tests. Therefore, the above concept should be replaced by the concept of quantity of injured parenchyma or by that of lesser or greater sensitivity of the liver function tests.

Despite the concept brought out by the experimental hepatic pathology that a minimal quantity of healthy liver parenchyma can accomplish some functional activities as normally, the analysis of our results, *considering the liver as a whole*, demonstrates that prothrombinemia detects earliest the damage to the hepatic cells, but that phosphatasemia is more sensitive in revealing biliary obstruction. As the severity of the damage increases both tests become abnormal and probably other less sensitive tests do also. This concept is in accordance with the idea of Ivy (14) of a *quantitative association* of the liver function tests instead of a *qualitative dissociation* of the liver's functions.

CONCLUSIONS

1. Chloroform anesthesia of 1 hour's duration produces in the dog a hypoprothrombinemia

mia and an increase of the alkaline phosphatase in the blood. The decrease in the prothrombin concentration precedes the hyperphosphatasemia and it reaches its maximum during the 24 to 48 hours following the anesthesia, while the highest value of the phosphatasemia is recorded between 48 and 120 hours following the anesthesia. By the 5th or 6th day the prothrombinemia has reverted to its normal value while the phosphatasemia remains above the normal level until the 10th to 13th day.

The value of the bilirubinemia is not greatly modified, ascending slightly and reaching its maximum between 24 to 48 hours and then reverting to normal.

All these changes are closely related to the degree of the hepatic injury produced by the chloroform.

2. Cholecystectomy and ligation of the common duct produce in the dog an increase of the serum alkaline phosphatase greater than in the experiments of chloroform intoxication (150 times the normal initial level). Fifteen hours following the operation the increase is very pronounced but the maximum value is reached at the end of a variable period which oscillates between the 4th and the 94th day. Then an irregular but constant decline begins and this decline lasts until the death of the animal.

The acid phosphatase activity parallels the alkaline but not in the same proportion. This increase is slightly greater than in the chloroform intoxication.

The prothrombinemia is late in revealing the hepatic damage due to the obstruction; only in the final period of the experiment is its value consistently low.

The bilirubinemia increases after the ligation of the common duct. The maximal concentration is obtained between the 4th and 52nd day following the operation. Afterward it stabilizes at a level slightly above the normal.

3. Cholecystectomy alone produces an increase of the alkaline phosphatase; the increments are greater than in the chloroform exsiliary obstruction. The maximum level is observed between the 10th and the 16th day

following the operation. Afterward a decline begins which reaches the normal level at the end of the 50th day.

The bilirubinemia does not suffer any variation.

The prothrombinemia suffers very slight variations during the first 24 hours after the operation and it is not related to the cholecystectomy itself.

4. A comparative study of the results demonstrates that prothrombinemia is more sensitive than phosphatasemia in denoting cellular hepatic lesion. The phosphatasemia is more sensitive than is prothrombinemia in detecting minimal biliary obstruction; i.e. one which could be designated as a functional biliary obstruction. As the severity of the damage increases, both tests become abnormal. It is concluded that it is more reasonable to accept the concept of a quantitative association of the liver function tests rather than of qualitative dissociation of the liver's functions.

were not surprised by the long lasting increased phosphatasemia after cholecystectomy though they considered it to be a sensitive index of the slight functional biliary obstruction connected with the dilatation of the intrahepatic bile ducts.

Our results confirm those of Drill (12) concerning the increase of the blood alkaline phosphatase following cholecystectomy in dogs. Although our studies were performed on only 2 dogs, the results closely coincide and warrant definite conclusions. However, in our animals the phosphatasemia returned to normal at an earlier period. This return to normal cannot be explained nor can the mechanism by which the functional changes of the intracanalicular pressure causes the phosphatasemia to rise.

The bilirubinemia does not change following cholecystectomy in dogs and this is not surprising if the great excretory capacity of the liver for bilirubin is recalled. Moreover, the increase of phosphatasemia is not necessarily associated with jaundice (15), and this is clearly shown in our cholecystectomy and chloroform experiments. These emphasize the concept of the existence of hepatic injuries which are not revealed by variations of the bilirubinemia.

Our comparative results show the existence of liver function tests which are very sensitive in their capacity to detect the hepatic damage, the course of the lesion, the reactive capacity of the liver, and the minimal biliary obstruction.

We have not attempted to evaluate the different tests as aids in determining the differential diagnosis of jaundice because, as is known, the dog is not an experimental subject for that purpose since he requires very extensive and severe hepatic damage or a total biliary obstruction to produce a degree of jaundice of certain intensity. However, this does not nullify the value of the results obtained from the comparative study of the bilirubinemia with the other tests.

In spite of the limitations imposed by the fact that it is not always possible to apply the results of animal experimentation to the human, our experiments demonstrate that: (1) prothrombinemia is more sensitive than

phosphatasemia in detecting cellular hepatic lesions, the course of the lesion, and the reactive capacity of the liver against injury, (2) phosphatasemia is more sensitive than is prothrombinemia in detecting the minimal biliary obstruction, i.e. one which could be designated as *functional biliary obstruction*. These statements apparently suggest the idea of the existence of a dissociation of the liver function tests which obviously implies the concept of a dissociation of the functions of the liver (metabolic and excretory). This is not erroneous so far as it is concerned with the reserve power of the liver. However, in accepting this idea one is forced to consider the existence of a systematized pathologic histology of the liver (pure forms of cellular injury and pure forms of canalicular injury) which, as is known, does not agree with the clinical reality.

The evidence points out that a given degree of hepatic injury does not equally affect the different functional activities of the liver in a quantitative manner, and, in order to gain knowledge of the course of any kind of hepatic damage, it is necessary to perform a series of different liver function tests. Therefore, the above concept should be replaced by the concept of quantity of injured parenchyma or by that of lesser or greater sensitivity of the liver function tests.

Despite the concept brought out by the experimental hepatic pathology that a minimal quantity of healthy liver parenchyma can accomplish some functional activities as normally, the analysis of our results, *considering the liver as a whole*, demonstrates that prothrombinemia detects earliest the damage of the hepatic cells, but that phosphatasemia is more sensitive in revealing biliary obstruction. As the severity of the damage increases both tests become abnormal and probably other less sensitive tests do also. This concept is in accordance with the idea of Ivy (14) of a *quantitative association* of the liver function tests instead of a *qualitative dissociation* of the liver's functions.

CONCLUSIONS

1. Chloroform anesthesia of 1 hour's duration produces in the dog a hypoprothrombinemia

mia and an increase of the alkaline phosphatase in the blood. The decrease in the prothrombin concentration precedes the hyperphosphatasemia and it reaches its maximum during the 24 to 48 hours following the anesthesia, while the highest value of the phosphatasemia is recorded between 48 and 120 hours following the anesthesia. By the 5th or the 6th day the prothrombinemia has reverted to its normal value while the phosphatasemia remains above the normal level until the 10th to 13th day.

The value of the bilirubinemia is not greatly modified, ascending slightly and reaching its maximum between 24 to 48 hours and then reverting to normal.

All these changes are closely related to the degree of the hepatic injury produced by chloroform.

2. Cholecystectomy and ligation of the common duct produce in the dog an increase of the serum alkaline phosphatase greater than in the experiments of chloroform intoxication (150 times the normal initial level). Fifteen hours following the operation the increase is very pronounced but the maximum value is reached at the end of a variable period which oscillates between the 4th and the 9th day. Then an irregular but constant decline begins and this decline lasts until the death of the animal.

The acid phosphatase activity parallels the alkaline but not in the same proportion. This increase is slightly greater than in the chloroform intoxication.

The prothrombinemia is late in revealing the hepatic damage due to the obstruction; only in the final period of the experiment is its value consistently low.

The bilirubinemia increases after the ligation of the common duct. The maximal concentration is obtained between the 4th and the 52nd day following the operation. Afterward it stabilizes at a level slightly above the normal.

3. Cholecystectomy alone produces an increase of the alkaline phosphatase; the increase is greater than in the chloroform experiments but less than in the experimental biliary obstruction. The maximum level is observed between the 10th and the 16th day

following the operation. Afterward a decline begins which reaches the normal level at the end of the 50th day.

The bilirubinemia does not suffer any variation.

The prothrombinemia suffers very slight variations during the first 24 hours after the operation and it is not related to the cholecystectomy itself.

4. A comparative study of the results demonstrates that prothrombinemia is more sensitive than phosphatasemia in denoting the cellular hepatic lesion. The phosphatasemia is more sensitive than is prothrombinemia in detecting minimal biliary obstruction; i.e. one which could be designated as a functional biliary obstruction. As the severity of the damage increases, both tests become abnormal. It is concluded that it is more reasonable to accept the concept of a quantitative association of the liver function tests rather than of qualitative dissociation of the liver's functions.

SURGICAL TREATMENT OF PANCREATIC CYSTS

RALPH ADAMS, M.D., F.A.C.S., and RANDAL A. NISHIJIMA, M.D., Boston, Massachusetts

PANCREATIC cyst is a disease of infrequent occurrence, although it is encountered often enough to merit some consideration in regard to accurate diagnosis and effective treatment. A review of the accumulated clinical records reveals that this diagnosis has been made in only 9 cases since the origin of the Lahey Clinic in 1926 to October 1, 1945.

Pancreatic cysts are usually observed in patients in middle life. They have been found to be present, however, at an early age, 1 case being reported in a 5 month old child (5). According to several reports in the literature, the two sexes are affected with equal frequency. (6, 18). In the present series of 9 cases there were 6 females and 3 males. The youngest was 18 and the eldest 71 years of age.

Robson and Cammidge classified pancreatic cysts into the following groups:

1. *Retention cysts*, which are lined with epithelium and are caused by obstruction in the pancreatic duct, smaller ducts, or acini.

2. *Proliferation cysts*, the result of proliferation of glandular epithelium followed by an accumulation of fluid. These are tumor formations (cystadenomas).

3. *Congenital cysts*.

4. *Hemorrhagic cysts*, secondary to necrosis and bleeding.

5. *Hydatid cysts*.

6. *Pseudocysts*, produced by trauma or degenerative changes of the interstitial tissue of the pancreas. These are distinguished from true cysts in that they are not within the substance of the pancreas but outside it and usually lie in the lesser omental sac. They have no epithelial lining.

7. *Dermoid cysts* (added by Judd, 12).

A summary of the types of pancreatic cysts which are found in this series is presented in Table I.

In the earlier literature, trauma was frequently mentioned as the etiologic agent in

the production of pancreatic cysts (10, 16, 17, 23). No accurate estimation of the percentage of frequency with which trauma was a causative factor can be made. In this group of cases, history of trauma was elicited in only 1 case.

More recently, the rôle of acute and chronic pancreatitis as the etiologic agent has been emphasized (12, 18). The pathogenesis is still undecided. It has been suggested that partial obstruction of the pancreatic ducts may lead to necrosis of the tissues by the pancreatic enzymes (4, 24). Archibald believed that pancreatitis may be the result of bile entering the pancreatic duct. In 3 cases of the present group, there was associated disease of the biliary tract. There was a previous history of jaundice in 3 of the cases. One patient had undergone elsewhere an exploratory laparotomy for acute cholecystitis; in another case, cholecystostomy had been done previously. Gallstones were noted in 2 of these cases at operation (Table II).

ANATOMY

An anatomical study shows the pancreas lying in the epigastrium and left hypochondrium in a retroperitoneal position, behind the serosal floor of the lesser omental sac, at the level of the first and second lumbar vertebrae. It is bounded posteriorly by the nonresilient posterior abdominal wall, and for this reason lesions of the pancreas are likely to extend forward in the direction of least resistance, and usually into the lesser sac. A diagrammatic sagittal section through the body of the pancreas demonstrates more clearly the various locations in which a pancreatic cyst may be found (Fig. 1).

The three most common locations occupied by pancreatic cysts are listed in order of frequency, according to Judd, Mattson, and Mahorner (13).

1. Cyst presenting between the stomach and transverse colon, and behind the gastroduodenal ligament.

From the Department of Surgery, The Lahey Clinic. Dr. Nishijima is fellow in Surgery, The Lahey Clinic.

TABLE I.—TYPES OF PANCREATIC CYSTS

Case	Sex	Age, years	Type of cyst
1	F	43	Papillary cystadenocarcinoma
2	F	71	Pseudocyst
3	F	58	Hemorrhagic cyst
4	F	39	Pseudocyst
5	M	45	Pseudocyst
6	F	51	Papillary cystadenocarcinoma
7	F	41	Pseudocyst
8	M	18	Pseudocyst
9	M	32	Pseudocyst

2. Cyst protruding into the lesser sac and presenting between the stomach and liver.

3. Cyst lying between the layers of the mesocolon, either behind the transverse colon or below it.

Rarely, these cysts may assume a position behind the descending colon, and may even descend into the pelvis.

In this series, the pancreatic cyst presented between the stomach and liver in 2 cases; posterior to the stomach and pressing against the gastrohepatic omentum in 2 cases; along the lesser curvature of the duodenum in the head of the pancreas in 3 cases; along the lesser curvature of the stomach in 1 case, and at the root of the mesocolon in 1 case.

DIAGNOSIS

Pain is the most frequent symptom. It is usually experienced in the right hypochondrium and epigastrium, and may be referred

to the back. Its intensity varies from a dull ache to a fairly severe pain requiring sedation. Frequently there may be only symptoms of pressure on the neighboring organs, especially on the stomach, with anorexia and epigastric discomfort after meals, which may be accompanied by nausea and vomiting and gaseous distention.

The presence of an abdominal mass situated above the level of the umbilicus, usually in the left hypochondrium, is the most helpful and reliable diagnostic sign. The surface of the cyst is likely to be smooth, tense, and immobile, except for those cysts located in the tail of the pancreas. Unless such a mass is palpable or demonstrable by roentgenographic study, a diagnosis of pancreatic cyst is difficult or impossible.

Roentgenologic examination is a major aid in the diagnosis of cysts of the pancreas. The presence of an enlarged duodenal loop, or a filling defect of the stomach, duodenum, or transverse colon produced by an extrinsic mass is evidence in support of a presumptive diagnosis of a pancreatic cyst.

Since a pancreatic cyst may extend into any part of the abdominal cavity, it must be distinguished from a distended gall bladder, omental or mesenteric cyst, hydronephrosis, a retroperitoneal tumor, an ovarian cyst, and cysts or tumors of the liver.

SURGICAL TREATMENT

There are three established procedures to be considered in the surgical treatment of pan-

TABLE II.—FINDINGS IN THE BILIARY TRACT IN 9 CASES OF PANCREATIC CYST

Case	Biliary tract history				Operative findings of biliary tract
	Cholecystitis	Gallstones	Jaundice	Previous operations	
1	o	o	o	o	Normal
2	+	+	+	o	Gall bladder scarred and small; a gall stone
3	o	o	o	o	Pancreatitis?
4	+	+	+	Cholecystostomy	Several small gall stones. Common bile duct dilated. No stones in common bile duct.
5	+	o	+	Exploratory laparotomy	Normal
6	o	o	o	o	Normal
7	o	o	o	o	Normal
8	o	o	o	Exploratory laparotomy	Normal
9	o	o	o	Exploratory laparotomy	Normal

and drainage had ceased. There was no sign of diabetes mellitus. On October 17, 1943, she died from a cerebrovascular accident.

CASE 3. A white female, aged 58, was seen in the clinic on May 18, 1943. For the past 5 years she had suffered from intermittent attacks of nausea. A roentgenogram taken by her physician was said to show a cyst of the liver. One week previously sharp pain occurred under the left scapula; the pain extended to the right side.

On physical examination, an irregular mass, which moved with respiration, was outlined just below the left costal margin.

All laboratory studies were negative.

An exploratory laparotomy was performed on June 14, 1943, by Dr. S. F. Marshall. A cyst about 10 centimeters in diameter was found extending from the body of the pancreas. It was located posterior to the stomach and extended upward against the gastrophrenic omentum. A smaller cyst, 2 centimeters in diameter, was located posteriorly and attached to the posterior abdominal wall. These two cysts were excised. Two cigaret drains were placed in the area through a stab wound in the left flank.

The pathologic report was hemorrhagic cyst with fibrous wall, probably the result of localized pancreatitis.

Follow-up examination on August 6, 1943, demonstrated mild diabetes. On November 29, 1943, a glucose tolerance test showed mild diabetes mellitus. Drainage had ceased on August 6, 1943.

CASE 4. A white female, aged 39, was seen at the clinic on November 15, 1943. About 2 years previously, cholecystostomy was performed elsewhere for attacks of right upper quadrant pain and vomiting. Many stones were removed from the gall bladder at that time. Mild jaundice was present before that operation. Since then she had had one attack of pain over the right upper quadrant, which lasted for 2 weeks. There was no jaundice.

Physical examination gave negative results. All laboratory studies were negative. A cholecystogram showed an outline of the gall bladder containing several very small negative shadows. Roentgenograms taken after a barium meal and barium enema were normal.

On January 14, 1944, operation was performed, by Dr. C. C. Engleman. A cyst, measuring about 2 centimeters in diameter, was found at the root of the mesocolon. Several small gallstones were found in the gall bladder. The common bile duct was dilated and contained no stones. The cyst was located at the inferior border of the head of the pancreas. The pancreas was hard, and the capsule thickened, suggesting a previous attack of pancreatitis. The cyst was excised. Cholecystectomy and choledochostomy were carried out. A cigaret drain was placed in the pancreatic area, and a Penrose drain placed in Morrison's pouch.

The pathologic report was cyst, with fibrous wall. Follow-up examination on February 16, 1944, showed no drainage from the site of the pancreatic

cyst. The patient has had no recurrence of symptoms or cysts.

CASE 5. A white male, aged 45, was seen at the clinic on February 2, 1944. In 1939, laparotomy had been performed elsewhere for cholecystitis. The gall bladder was not removed. However, an appendectomy was done. Following this he had had abdominal pain intermittently. Three weeks previously he had had an attack of jaundice which lasted for 3 days. He had lost 30 pounds in weight in 2 months.

Physical examination gave negative results. All laboratory studies were negative except for a glucose tolerance test which was suggestive of diabetes mellitus. A cholecystogram was negative. A roentgenogram taken after a barium meal showed an enlargement of the duodenal loop with compression of the first portion of the duodenum.

Operation was performed on March 1, 1944, by Dr. Ralph Adams. A cyst about 6 centimeters in diameter was found arising from the head of the pancreas and occupying a position in the curve of the duodenum. This cyst was anastomosed to the jejunum as described previously.

The pathologic report was fibrosis and chronic inflammation.

The patient was discharged on March 18, 1944, after an uneventful convalescence. He was seen on April 28, 1944, and at that time he had no symptoms of any distress. On May 5, 1944, a gastrointestinal roentgenologic study was done. This showed a decrease in the size of the cyst, with no evidence of any barium in the cyst cavity. On August 15, 1945, another fluoroscopic and gastrointestinal roentgenogram again showed a decrease in the size of the cyst; no barium entered the cyst.

CASE 6. A white female, aged 51, was seen at the clinic on May 22, 1945, complaining of epigastric discomfort for the past 3 years. The gnawing ache in her epigastrium was aggravated by eating. About 6 months previously she noticed a mass in the left upper quadrant which steadily increased in size.

Physical examination showed a mobile smooth mass in the left upper quadrant. All laboratory studies were negative. Fluoroscopy and gastrointestinal roentgenograms showed a deformity of the stomach produced by a large mass in the left upper quadrant. An intravenous pyelogram was normal.

Operation was performed on June 23, 1945, by Dr. Ralph Adams. A large cyst, 12 centimeters in diameter, was found arising from the body of the pancreas. The stomach was displaced downward. The cyst contained many papillomatous masses, and frozen section showed it to be carcinomatous. Cystojejunostomy was performed as described previously.

The pathologic report was papillary cystadenocarcinoma.

The patient made an uneventful convalescence and was discharged on July 15, 1945. She was seen in the clinic on August 15, 1945, and had no complaints. The mass was still palpable. Fluoroscopy and gastrointestinal roentgenograms showed the cyst with no barium entering it.

Some surgeons have objected to an anastomosis between the pancreatic cyst and the gastrointestinal tract in the belief that the intestinal contents may enter and lead either to suppuration or to an activation of the enzymes in the true pancreatic cysts. They depended on the resorptive power of the gall bladder to remove the fluid produced by the cyst. Walzel performed a primary anastomosis between the cyst and the gall bladder and, to prevent a reflux of bile, the cystic duct was ligated. The rationale for the cystic duct ligation is difficult to understand. Neuffer performed a similar operation but did not ligate the cystic duct. Meyer obtained satisfactory results using the technique of Neuffer.

SURGICAL PROCEDURE

In 2 cases encountered in the clinic in the past 2 years, the patients were treated by doing a cystojejunostomy. The results to date have been very satisfactory and the surgical procedure is described below.

Exposure of the pancreatic cyst is made either through the gastrocolic or the gastrohepatic omentum. A rent is made in the mesocolon, through which a loop of jejunum about 35 centimeters from the ligament of Treitz is drawn. The jejunal serosa is sutured to the cyst wall with a row of interrupted silk sutures. The cyst is then aspirated and an incision 2.5 centimeters in length is made in its wall. A similar parallel incision is made in the jejunum. A posterior layer of sutures unites the cyst lining with the intestinal mucosa. A row of interrupted Connell sutures is placed, thus inverting the anterior walls of the cyst and jejunum. This is reinforced with another layer of interrupted silk sutures. Two sutures are placed at each angle to buttress the jejunum to the pancreas. A jejunojejunostomy of the efferent and afferent loops is then made about 15 centimeters from the ligament of Treitz.

CASE REPORTS

CASE 1. A white female, aged 43, was seen at the clinic on July 19, 1927, because of soreness and pain over the right upper abdomen, which had been present since April 9, 1927. This had persisted for several days and was not related to food intake. On May 9, 1927, she began to have sharp pain over the same

area, accompanied by nausea and vomiting, and morphia was required for relief. On June 3, 1927, a mass appeared in the left upper quadrant.

Laboratory studies were negative. Fluoroscopic examination showed an extrinsic pressure defect on the stomach, between the antrum and media, causing an hour-glass deformity. The interpretation was pancreatic tumor.

On July 22, 1927, operation was performed by Dr. F. H. Lahey. The approach was made through the gastrohepatic omentum. A cyst about 7 centimeters in diameter was found projecting from the body of the pancreas. The cyst was opened, and the friable contents removed. The lining was painted with iodine, and a cigaret drain inserted. The edges of the cavity were sutured to the peritoneal edges around the drain.

The pathologic report was papillary cystadenocarcinoma of the pancreas.

There was no postoperative complication. The patient was discharged on the tenth day with a discharging sinus.

Follow-up examination of this patient showed a small discharging sinus on August 7, 1927. On September 17, 1927, there was no sign of diabetes mellitus. The patient died December 11, 1927, from metastasis of this carcinoma.

CASE 2. A white female, aged 77, came to the clinic on September 25, 1941, because of an abdominal mass of 3 years' duration. She complained of occasional dull pain in the right upper quadrant of the abdomen which occurred after eating. She had had a short period of jaundice about 4 years previously. In 1932 she was operated upon for pancreatitis. The findings at this operation are not available.

Physical examination showed a tumor mass filling the upper abdomen, extending about 5 centimeters below the umbilicus.

Laboratory studies were negative. A partial gastrointestinal roentgenologic examination showed the stomach to be displaced by an extragastric mass lying along the lesser curvature. An intravenous pyelogram showed displacement of the left ureter by this mass, with probable pressure on the left renal pelvis.

Operation was performed September 29, 1941 by Dr. S. F. Marshall. A cyst about 25 centimeters in diameter was found lying posterior to the lower portion of the stomach and one of the loops of the small bowel. Four liters of fluid was removed from the cyst. A stab wound was made in the left flank. The wall of the cyst was brought out through this incision and sutured to the peritoneum and muscle. It was likewise sutured to the skin with interrupted black silk sutures. Two cigaret drains were placed into the interior of the cyst. The gall bladder was small and scarred, and contained two stones.

The patient was discharged on October 19, 1941, and was seen in the clinic thereafter. The drainage continued until May 21, 1942. The patient was seen on July 16, 1943; there was no recurrence of the cyst

SEVERE BURNS: CLINICAL FINDINGS WITH A SIMPLIFIED PLAN OF EARLY TREATMENT

ROBERT ELMAN, M.D., F.A.C.S., C. R. MERRY, M.D., CELSUS E. BEGUESSE, M.D., and RAPHAEL TISDALE, M.D., St. Louis, Missouri

DESPITE the tremendous amount of clinical and experimental study, much of it stimulated by the war, there is considerable confusion in the minds of many surgeons as to the preferred method of immediate and early treatment when confronted by a serious thermal injury. The purpose of the present communication is to describe the clinical findings following a plan of treatment reduced to its simplest details. It must be emphasized, however, that no plan can take the place of careful clinical study of the individual case. Nevertheless, the results obtained seem sufficiently good to suggest that therapy based on such a plan may be preferable to more intricate and complicated methods. The large literature on the treatment of burns will not be reviewed; it has been well done by Harkins and others.

SELECTION OF MATERIAL

During the 2 year period of study 112 burn cases were considered severe enough to justify admission of the patient to the hospital. Only about half, or 55 cases, were selected for analysis. First, no case was included in which the patient did not arrive in the hospital within a few hours of injury and in which he did not remain in the hospital until full treatment was carried out. Second, in order to study only severe cases, all patients with

burns involving less than 10 per cent of the body surface were excluded, with the exception of 4 patients in this group requiring skin graft.

PLAN OF THERAPY

On entrance into the receiving room all exposed burned areas were covered with a sterile sheet and blanket. Morphine or codeine injections were not given as routine but only to control pain or apprehension, respectively, when present. As routine a prophylactic dose of antitetanus serum was injected. Full treatment was carried out in the following chronological order after arrival at a dressing room off the surgical wards.

Intravenous injections. It was accepted as axiomatic that the voluntary oral route for the administration of needed food and fluid elements was preferable to the parenteral channel, which should be employed only when necessary. In other words, only when the oral route was ineffective, particularly in meeting acute deficits, were intravenous injections used. Plasma transfusions were therefore not given as routine, were not based on the extent of the burn, but were used primarily for the treatment of shock when present, or prophylactically when shock seemed imminent. This routine required constant observation of the patient, particularly during the first 24 to 48 hours, inasmuch as some patients entered the hospital in good general condition, but developed signs of shock after several hours, or responded to one transfusion only to fall into shock again later. Although pronounced hemoconcentration is

From Washington University Medical School and Homer G. Phillips Hospital, Saint Louis, Missouri.
The work in this paper was done under a contract recommended by the Committee on Medical Research between the Office of Scientific Research and Development and Washington University.

CASE 7. A white female, aged 41, was seen at the clinic on June 29, 1945, complaining of weakness, dizziness, and attacks of unconsciousness. Studies showed her to have an islet cell tumor of the pancreas. On July 5, 1945, an operation was performed, and an islet cell tumor in the head of the pancreas was removed. The pathologic report was islet cell adenocarcinoma.

On September 10, 1945, pain appeared in the left hypochondrium. This pain was fairly severe and extended to the back. Roentgenographic examination of the stomach showed a crater deformity on the posterior wall of the fundus of the stomach.

On October 4, 1945, an exploratory laparotomy was performed by Dr. S. F. Marshall. A collection of slightly cloudy fluid in a thin walled cyst was found in the left subphrenic area, and also between the stomach and pancreas. The pseudocyst was evacuated. The wound healed on removal of the drain, and she was discharged on the nineteenth postoperative day, symptom-free. No evidence of metastasis or recurrence of adenocarcinoma of the pancreas was found.

CASE 8. A white male, aged 18, was seen at the clinic on January 22, 1936, complaining of a draining abdominal sinus for the past 3 months. About 3 months previously following an upper abdominal injury, an exploratory laparotomy was performed elsewhere, and a large hematoma was found lying between the two layers of the gastrosplenic omentum. The abdomen was closed without drainage. The postoperative course was complicated by the appearance of a discharging sinus.

Physical examination showed a discharging fistula in a healed upper right rectus incision, surrounded by an area of irritated skin.

On January 22, 1936, a gastrointestinal roentgenogram, taken after lipiodol injection of the sinus, showed the fistula to be in the region of the head of the pancreas.

Conservative management was then instituted with diet, alkaline powders, and helladonna. When no improvement was shown under this regimen, the pancreatic fistula was transplanted into the jejunum on March 16, 1936 (operation performed by Dr. F. H. Lahey). The postoperative course was uneventful, and the patient was discharged from the hospital on April 3, 1936.

In August 1936, another abdominal injury necessitated another exploratory laparotomy elsewhere. The fistulous tract into the jejunum was not injured.

The patient was symptom-free until July 22, 1941, when severe pain developed in the upper left portion of the abdomen, accompanied by nausea, vomiting, and a temperature of 102 degrees F. He was then admitted for study. A diagnosis of subacute pancreatitis was made. Following a period of medical management, he was discharged on October 10, 1941, improved.

CASE 9. A white male, aged 32, was seen at the clinic on June 18, 1944, complaining of a draining pancreatic fistula of 15 months' duration. In May

1942, an exploratory laparotomy was performed elsewhere for acute pancreatitis. No drainage was carried out. In March 1943, this patient was operated on elsewhere, presumably to have a cholecystectomy performed for a nonfunctioning gall bladder. A pancreatic cyst was found, however, and since it was too small to be marsupialized, it was opened and drained with a cigaret drain. This drain was removed 3 months later. Since then the sinus has continued to drain, occasionally requiring probing to relieve the obstruction which caused a great deal of pain.

Physical examination showed a healed upper right rectus incision with a small fistulous opening at the upper end of the scar. The surrounding skin showed a chronic irritation. All laboratory studies were negative.

On June 20, 1944, the fistula was transplanted into the jejunum, Dr. F. H. Lahey performing the operation. The postoperative course was normal, and the patient was discharged on July 19, 1944.

Follow-up by correspondence showed this patient to be symptom-free until December 19, 1945, when he revealed that he has been having left hypochondriac pain extending to the back for the past month. He is to be readmitted for further study.

SUMMARY

The literature on pancreatic cyst is reviewed. Nine additional cases are reported. The anatomic, physiologic, and pathologic features peculiar to this lesion are enumerated. The symptoms, signs, and examinations upon which a diagnosis may be made are discussed. Internal drainage by means of cystojejunostomy is recommended when extirpation of the cyst is not feasible, and the technique employed in establishing this anastomosis is described.

Chemotherapy. No local chemotherapy was used whatever. As a routine, sulfathiazole, 1/10 gram per kilogram per day was given by mouth. However, if there was any contraindication to the use of sulfathiazole, it was not given. In a few patients penicillin was used early in doses of 160,000 units per day, but more commonly and effectively later in preparation for skin grafting. All primary chemotherapy was discontinued by the end of the first week unless there was evidence of infection.

Preparation for skin graft. Preparation for skin graft presented the greatest problem in the treatment of full thickness burns and will not be described in this paper. All sorts of methods were used, including proteolytic ferments. In general, wet saline packs were found to be the most effective, although they left much to be desired.

Nutrition. Though listed last, attention to nutrition, including oral fluid intake, was given a high priority in the present plan of treatment. Practically all patients suffered great thirst on admission and it was not necessary to urge them to ingest a large quantity of liquids. From the very beginning these liquids were of high nutritional value and included high protein and calorie drinks, ice cream, etc. A high intake of sodium chloride based on the experimental findings of Rosenthal and the clinical studies of Fox was not a part of the present plan. It is likely, however, that all patients did ingest large amounts of electrolyte in their food and drink. Vomiting was infrequent, but when it occurred was usually transient or beneficially influenced by plasma transfusions, in patients suffering from circulatory impairment and in whom vomiting was a manifestation thereof.

The assurance of a good nutritional intake was not left to chance, to a dietary order, or to the efforts of the dietician. A specific amount of fluids and food was ordered just as in the case of medication. Moreover, the intake was checked each day to be sure that most of it was taken. In addition, the urinary output was measured and if it fell below 1000 cubic centimeters the intake was checked, and if inadequate, efforts were made to see that it was maintained at several liters or more a day.

If the patient refused to eat a normal, well balanced diet, a high protein milk diet was ordered which in one liter contains 100 grams of protein and 1000 calories, which was considered as the daily minimum for an average sized adult. When possible the patient was urged to take 200 grams of protein and 2000 or more calories, particularly after the first few days. The threat of tube feeding was used in many patients, but was not employed in any of the present cases. Large amounts of ascorbic acid were given, 1 gram or more a day. An important feature of a good nutritional intake is that it start at once, i.e., as soon as the patient is dressed. Prevention is far easier than cure. If severely burned patients are allowed to lose much body tissue, the problem of restoration is extremely difficult even with a large dietary intake. The importance of maintaining good nutrition in burned patients has been well and extensively studied by Levenson, Davidson, Lund, and Taylor.

Early movement of the patient was encouraged and, unless the lower extremities were involved, the patient was urged to get up out of bed as soon after the dressings were applied as possible. If the lower extremities were involved, an attempt was made to get the patient into a wheel chair. When the upper extremities were involved it was obviously necessary to provide frequent nursing care in order to insure an adequate nutritional intake.

CLINICAL FINDINGS

Because of the tremendous variation in the findings it is difficult to summarize them adequately. To aid in the analysis, all patients were divided into three groups and the main details summarized in three tables as follows: Table I, those which healed without the use of skin graft; Table II, those which healed with skin graft; Table III, fatal cases.

Text figures of changes in the red count will be presented to illustrate findings of special significance. Reference will be made to them in the following general discussion of the results of the study.

Systemic manifestations on entrance. The most common symptom was thirst, which was almost universally observed in practically all

often used as an indication for the injection of plasma, and did nearly always accompany the appearance of shock, it was used as a routine indication in the present series only when the red count increased progressively. Many patients with hemoconcentration were not in shock and recovered without any intravenous therapy. This fact was also true in several cases with a large involvement of the body surface. If there were no systemic manifestations other than moderate hemoconcentration, plasma was, with few exceptions, withheld. Whole blood was given only when evidence of anemia developed or in conjunction with skin grafting. Saline and glucose solutions were injected only in connection with plasma transfusions and in the only case with persistent vomiting. A high fluid intake by mouth was maintained from the beginning, as described in detail under nutrition.

The amount of plasma given depended on the severity of the shock. No rigid formula was used, but for an adult at least 500 cubic centimeters was started as the initial dose. In the most severe cases larger amounts, e.g., 20 cubic centimeters per kilogram of body weight, or about 1500 cubic centimeters for an average sized adult, were injected. The rate of administration was quite rapid to combat shock, and more plasma was injected if the clinical response was not sufficient, or was repeated if circulatory impairment recurred.

Débridement and cleansing. No débridement whatever was carried out in any patient even in several in whom home remedies had been applied, such as talcum powder, sulphur ointment, lard, baking soda, bluing, and molasses. However, none of the burns was grossly dirty. Blisters were left intact and no attempt whatever was made to remove shreds of skin or other loose tissue. Cleansing was gently carried out with soap and water, but largely over the intact skin next to the burned area. Omission of débridement in fresh, clean burns was first formally recommended by Cope as a result of treating the victims of the Coconut Grove disaster; its use in the present plan was based largely on his excellent results.

Dressing. The basic principles involved in the application of a dressing to the burned area in order to avoid infection was thoroughly

described by Colebrook and his coworkers. Their excellent results prompted the use of these principles. The first and most important principle was the maintenance of scrupulous aseptic technique, the same, indeed, as that employed in the operating room. A rigidly observed detail was the masking of the patient and of all personnel during dressing. Next to the burn a layer of fine mesh gauze or other fabric was applied with or without some type of ointment. Over the primary layer of fabric a bulky layer of gauze was applied and held in place with a firm circular bandage. Pressure by means of cotton waste or elastic bandage was used in a number of cases, but was not adopted as a routine. A plaster splint for the extremities was sometimes included in the dressing. A bulky dressing, however, was always used because it absorbed discharges and seemed partly to immobilize the part.

Another important detail was the application of dressing well beyond the obviously burned area of skin, for reasons mentioned below. A third feature of the dressing was the fact that it was allowed to remain in place as long as possible, usually 10 to 14 days. It was removed earlier only when necessary because of pain, high fever, or excessive discharge. It was found advisable to explain this policy of infrequent dressing to the patient and the family in order to prevent a tendency for them to complain of neglect, which frequently occurred unless the plan was explained beforehand.

Burns about the buttock. In burns in the general region of the anus, particularly in children, a constipating regimen with purgative was instituted and maintained for about a week. After this period enemas were ordered and given each day at a specific time when a member of the house staff was present, so that the dressing could be changed at once if necessary in order to prevent undue contamination. This seemed to work very well and probably played an important part in the prevention of secondary infection.

Oxygen inhalations. Patients who showed evidence of pulmonary injury or those suffering from respiratory distress for other reasons were placed in an oxygen tent during the first few days.

*Patient malnourished and probably anemic at time of burn.

†Only patients of this group in shock or with toxemia soon after admission to hospital

absent in all of the patients summarized in Table I, all but 5 of whom suffered from hot water burns, even though the extent of the burn in this group was as great as 40 per cent of the body surface. Even in the group of patients requiring skin graft (Table II) evidence of shock and toxemia was present in only 2 cases. On the other hand, these signs were present in 8 of the 12 fatal cases (Table III). The term shock was applied to any patient suffering obvious circulatory impairment. The term toxemia was used when stupor, irrational behavior, restlessness, delirium, and high fever were observed. In a few cases there was moderate transient lethargy, but this was not listed as a systemic manifestation.

Hemoconcentration was studied in practically all cases by taking frequent red cell counts or hematocrit measurements. Great variations and differences were detected in the behavior of the hemoconcentration, 6 examples of which are shown in the accompanying text figures. It will be noted by consulting these and the tables that flame and hot water

burns exhibit differences in both the frequency and duration of hemoconcentration. In general, fewer flame burns showed increases, but the process seemed more prolonged yet less intense than in hot water burns.

Not listed was the relationship between the character of the necrotic skin and the presence and severity of systemic manifestations, including fever. In general, moist necrosis was much more likely to present signs of toxemia whereas a dry, hard necrosis was associated with fewer systemic signs (8). This was particularly true after the first 24 to 48 hours.

Estimation of the degree and depth of the burn. The area of the skin actually burned was nearly always greater than that estimated by inspection at the time of entrance. This was true especially of hot water, but also of flame and flash burns. This finding was of obvious practical importance because it emphasized the need for applying the dressing well beyond the visible burned skin. Otherwise, exposed injured skin would become apparent within 2

of the patients. Second in frequency was a complaint of coldness and chilliness, which practically always disappeared as soon as the burned area was covered by sterile sheets and blankets and permanently controlled by the application of the dressing. Pain was strikingly rare, which is of extreme interest in view of the almost universal use of morphine in the treatment of burns. Indeed, many of the patients were rather apathetic and had no complaints. In only 9 of the 55 cases herein reported was morphine used, and in many of these merely to control restlessness rather than pain. In an unpublished series of observations on human volunteers this finding was confirmed, i.e., the intense pain stimulus

at the time of the burn was replaced by a dull ache which lasted for a short time and then gradually disappeared. It may be that certain other types of burns not observed in the present series are accompanied by lasting severe pain, but this certainly was not true of the patients we observed. The possible dangers and misuse of morphine in severe injuries has been well discussed by Beecher.

Vomiting occurred in only 2 of the nonfatal cases and in neither of them did the vomiting interfere with feeding because it disappeared within 24 hours. In the fatal cases vomiting was more frequent; 6 of the 12 patients vomited, but in only 1 was it persistent (Case 51). Evidence of shock and toxemia was

* Estimate only approximate in patients dying soon after admission

or 3 days, invariably become infected, and act as a portal of entry for bacterial invasion.

The depth of the burn was also difficult to predict by inspection alone even at the time of the first dressing. By experience, however, it was soon obvious that the kind of thermal agent was of primary importance. For example, hot water seldom produced full thickness burns, only 2 out of 21 in this category requiring skin graft. Moreover, if one consults Table I, listing the burns which required no skin grafting, 19 of the 26 were due to hot water. On the other hand, in Table II, listing those which required skin graft, in all but 2 of the 17 cases a flame or flash was the responsible thermal agent. It should be emphasized, however, that 7 of the flame burns healed without skin graft, even though in 4 of them the burn had involved 25 per cent or more of the body surface (Cases 1, 10, 11, 26). It was also observed that even in extensive flame burns requiring skin graft the area was frequently smaller than expected. This seemed directly connected with the absence of infection and with the fact that the patient maintained a good nutritional intake from the beginning. Entirely apart from the food in-

take during treatment, the nutritional status of the patient at the time of injury also played an important part in the extent of skin requiring graft. Many of the burned patients were obviously malnourished and in them the depth of the burn always seemed to be much greater than in healthy individuals.

Type of ointment. Observations made with various types of greasy ointments showed in general relatively little difference even when similar areas were compared. However the best results seemed to follow the use of a water soluble carbowax ointment made up according to directions supplied by Dr. F. L. Meleney. Comparisons were also made between petrolatum-impregnated gauze and dry fine mesh gauze. In general, the latter, placed next to the skin, was followed by a drier wound but removal was more difficult and painful. Petrolatum, if applied sparingly in fine mesh gauze, proved fairly satisfactory; however, if an excessive amount of it were applied, which was more likely if coarse mesh gauze were impregnated with it, there was much more maceration of tissue and evidence of irritant action, as shown by greater discharge and apparently more necrosis.

Incidence of infection. The most striking observations made in the present series of cases was the relatively low incidence of infection. This was obvious at the time of the first change of dressing even when a period of 2 weeks had elapsed. In many cases the burned areas were dry and healed. Even when the skin showed moist necrosis there was rarely any pus or cellulitis. This low incidence of infection is also shown by the relatively low incidence of fever, which is shown in the tables herewith presented. For example, 19 of the 43 healed cases showed no fever at any time and 29 no elevation above 101 degrees F. More striking was the fact that at the time of the first change of dressing only one patient had a fever of 102 degrees F. or above, only 8 had 101 degrees F., 7 had 100 degrees F.; in 27 of the 43 the temperature was normal.

Another of the advantages of infrequent dressings was a reduction in the amount of routine nursing and professional care. This made it possible to employ the available nursing service for other purposes, notably maintenance of a good fluid and food intake, psychotherapy, and early movement and ambulation of these patients.

Fig. 1. Case 6. Three year old male, hot water burn involving 30 per cent of the body surface, which healed without skin graft. Note pronounced hemoconcentration on entry and its prompt subsidence without parenteral fluids. There were no systemic manifestations at any time except moderate lethargy for the first 24 hours. Fluid and food intake excellent from the beginning.

Parenteral injections. Only 10 of the 43 patients with healed burns were given plasma or blood transfusions as part of their early therapy, and of these 9 had flash or flame burns. Many extensive burns healed completely and satisfactorily without the use of plasma. This was true particularly of hot water burns, even when the red count was

Fig. 2. Case 10. Forty-nine year old female, flame burn involving 40 per cent of the body surface, which nevertheless healed without skin grafting. Note the slow appearance of moderate hemoconcentration, which reached its maximum only after 48 hours and disappeared slowly by the 7th day. No parenteral fluids were used, but the patient took a high caloric, high protein diet from the beginning.

Fig. 3. Case 18. Fifty-one year old male, hot water burn involving 45 per cent of the body surface, which healed without skin graft. Note the prompt correction and probable overcorrection of hemoconcentration following two plasma transfusions. The anemia showed some spontaneous correction but was subsequently treated with whole blood transfusions. The general condition was good throughout the hospital stay.

significantly, and once greatly elevated (Figs. 1 and 2). The effect of plasma in correcting the hemoconcentration is well demonstrated in several cases shown in these figures. It should be mentioned, however, that 2 of the fatalities (Cases 50 and 51) might have been avoided had plasma been given or repeated, although in both patients pulmonary complications may have contributed to the fatal outcome. It should be noted that when plasma was needed large volumes were usually used. For example, in Case 52, 6 liters were used before the level of the red count remained normal.

Rapidity of healing. As compared with our previous experiences, the patients in the present series, even many with extensive burns, healed more rapidly and required less skin grafting. This seemed undoubtedly the result of the relative decrease in infection; infection itself is known to convert second degree into third degree burns, and thus increase the number requiring skin graft. It was striking that several of the extensive, fairly deep burns healed spontaneously or required only a small skin graft. Perhaps of equal importance in the rapidity of healing, as

already mentioned, was the high nutritional intake. On several occasions, patients whose nutrition was particularly well maintained by a high food intake had deep burns which looked as if they would require extensive skin graft, but which healed spontaneously without contracture, or needed only small coverage.

Removal of slough. The results in this group of patients were unsatisfactory and accounted for the long period of hospitalization, as shown in Table II. It is probable that further research will improve the present methods.

Anemia. Anemia was observed in only 8 of the 55 cases. In 6, the anemia was only moderate; the lowest count was between 3 and 4 million. In only 2 cases did the red count fall below 3 million. Three of the 8 cases resulted fatally, and this included one of the patients with a count under 3 million. On the other hand, the patient with the lowest red count, 2.4 (Case 18) recovered uneventfully. Whole blood transfusions as well as packed or suspended red cells were used in all of these cases, but not as an initial form of therapy, inasmuch as anemia was not found during the first 24 hours, and in only 1 case (Case 18, which recovered) as early as the second day.

Fig. 4. Case 30. Twenty-one year old female, flame burn involving 40 per cent of the body surface requiring some skin grafting. Note the hemoconcentration on admission which responded promptly to a plasma transfusion only to recur within 24 hours. Spontaneous correction occurred thereafter, undoubtedly aided by an excellent fluid and food intake by mouth.

Blood chemical changes. Plasma protein determinations were made in many of the patients but will not be summarized in this report. Frequent red cell counts or hematocrits were made and form the basis for many of the graphs presented herein. The non-protein nitrogen of the blood was determined in many cases and frequently was found to be elevated, returning to normal with satisfactory progress of the case. In two of the fatal cases the rise was progressive until death.

Fatal cases. Inasmuch as the saving of life comes first in treatment, failure to do so under the present plan of treatment deserves special analysis. Scrutiny of the 12 fatal cases listed in Table III indicates that 6 of them were flame burns which involved 60 per cent or more of the body surface and might therefore be said to be fairly hopeless from the start. In spite of this, one of these patients survived for 7 days, another for 4 days, and a third for 12 days, the 3 others dying within a few hours after admission. The remaining 6 fatal cases might perhaps be called preventable failures. In 1, the patient died 3 months after the burn

following a fatal (Rh?) transfusion reaction. In another (Case 46) the patient survived for 30 days even though the burn involved 56 per cent of the body surface. Progress was satisfactory even though tetanus developed (in spite of the prophylactic injection of serum on admission) and apparently responded well to therapy. While it may have been partly the cause of death, the presence of an old Pott's disease of the spine suggested that miliary tuberculosis may have developed terminally. In another case involving 40 per cent of the body the patient survived 14 days (Case 54). This patient presented great difficulty throughout his hospital stay, largely because of repeated hemorrhage from the burned area. The burn was quite severe, inasmuch as the deep fascia was exposed at numerous places. Bleeding might have been due to hypoprothrombinemia. Unfortunately, no observations thereof were made. Another fatal case involving only 30 per cent of the body occurred in a 2 year old female who lived only 2 days (Case 53). The patient entered somewhat stuporous and this increased until the time of death without any fever. Respirations were

Fig. 5. Case 33. Twenty-four year old female, flash burn involving 30 per cent of the body surface, requiring some skin grafting. Complete healing by the 44th day. Note the persistent hemoconcentration permanently corrected only after three plasma transfusions.

labored and it was assumed that severe pulmonary damage had occurred, inasmuch as the child had been trapped in a burning house and undoubtedly inhaled a good deal of noxious gases as well as actual flame.

The remaining 2 cases (Cases 50 and 51) more than the others may be said to represent preventable failures in so far as the use of more plasma may have made a difference. However, pulmonary damage may have been partly responsible for the fatal outcome inasmuch as both patients were burned in the same accident, an explosion which occurred in a closed room and undoubtedly made inhalation of heated gases inevitable. Autopsy was done in only 1 case, but showed inflammation and deposition of soot down as far as the bronchi, as well as other evidence of pulmonary injury. Symptoms of circulatory impairment were present on admission in 1 case, but responded dramatically to a plasma transfusion, only to recur during the night. It was assumed to have been present for many hours before the second transfusion was started, because the patient died before very much plasma could be administered. In the other case (Case 50) surgical shock appeared only several hours after admission, and the patient died before transfusion could be started.

The frequency of vomiting, evidence of shock and toxemia in the fatal cases, should emphasize the importance of these clinical findings. These manifestations in many cases proved a more significant indication of the seriousness of the burns than the extent of skin involved. Moreover, all of the fatal cases were flame or flash burns. These factors are emphasized because they suggest that special study and treatment be accorded such patients from the beginning in order to save more of them if possible, particularly those involving a relatively moderate extent of the body surface.

COMMENT

On the basis of the present and previous studies, it has become increasingly evident that the systemic manifestations in severe burns including hemoconcentration, sensorial changes, circulatory impairment, and even fever and renal damage vary tremendously from case to case. Moreover, it seems clear that any attempt to correlate these differences with the degree of tissue damage must be based on more information than that given in the usual designations of extent of body involved and the terms first, second, and third degree burns. It would seem worth while evaluating carefully in each case the actual nature of the burn stimulus as well as its probable duration. The type of skin damage produced by various thermal injuries has received little study, particularly in fatal cases in which complete microscopic study of the skin is possible. Such information is needed if we are to explain the great variations in the systemic effects of severe burns and to save more of the fatal cases with as simple and effective therapy as possible.

Variations in the actual thermal injury may be classified into at least three groups: (1) The degree of temperature of the thermal agent may vary from 70 degrees C. in a hot water burn to several thousand degrees in a flash burn. (2) The duration of the increased temperature varies from a fraction of a second in some flash burns to many seconds in the case of hot water or flame; it undoubtedly lasted many minutes in the case of the victims trapped in the Cocoanut Grove or Hartford

Fig. 6. Case 40. Seven year old male, flash burn involving 30 per cent of the body surface. Note that on admission there was absence of hemoconcentration and definitely elevated blood pressure. The general condition was good. After 12 hours typical surgical shock developed with cold extremities, rapid pulse and unmeasurable blood pressure. This was accompanied by hemoconcentration. A rapid plasma transfusion of 1000 c.c. (30 c.c. per kilogram) effected a dramatic clinical improvement, and as shown in the chart, a prompt restoration of blood pressure and correction of hemoconcentration. Skin graft was eventually necessary. ●—●, Blood pressure; ○—○, red blood cells.

circus fires. (3) The part of the body involved also contributes to variations as, for example, the relative resistance of the face as compared to the hands, due undoubtedly to the differences in their blood supply and tissue tension.

Classification according to the thermal agent itself, e.g., flame and hot water burns, may explain many of the differences. For example, in the present series none of the 21 hot water burns proved fatal and only two required skin graft, yet a third of them involved 30 per cent or more of the body surface. Moreover, more of them exhibited hemoconcentration than did the flame and flash burns. Nevertheless, all of the fatal cases were flame and flash burns and all but one showed hemoconcentration. In contrast to the relative infrequency of skin graft even with extensive hot water burns, two thirds of the surviving flame burns required skin graft even though

many involved small areas of the body. In spite of the frequency of hemoconcentration in the hot water burns the incidence of fever was less pronounced, i.e., half of them showed none during their entire stay. By contrast, only a third of the flame and flash burns were afebrile during their entire stay. It should be emphasized that fever was only occasionally associated with other manifestations of infection; in most cases it was probably due to absorption from devitalized tissue or extravasated serum.

The satisfactory results which can be obtained with the simplest of dressing were well demonstrated in the present series of cases. Despite the hundreds of different ointments recommended for application next to the burned skin, it would seem that none is really required. Much more important is the meticulous avoidance of droplet and other

contamination during the dressing. The fundamental fact that much of the infection in burns can be traced to bacteria which reach the burn *after the patient enters the hospital* was established by Cruikshank over 10 years ago. Its truth and practical application in dressing burns seem amply shown in our findings.

The rather limited use of intravenous injections in the present plan of therapy, demands special scrutiny. While such treatment is always complicated and should be minimized as far as possible in formulating a simplified plan of treatment, it should never be withheld when indicated. The most absolute indication is, of course, the possibility in combating, in the severe cases, any tendency toward a fatal outcome. How can one tell? The present observations have certainly indicated that many extensive burns will undoubtedly heal promptly and satisfactorily without such intravenous injections. On the other hand, there is always the possibility that fatalities may result from such a policy. From our observations as reported herein it is evident that constant observation is necessary during the first 24 to 48 hours in any patient with a flame burn exhibiting such systemic manifestations as vomiting, severe sensorial depression, actual or incipient circulatory impairment. These manifestations are of grave import even when the burn involves but 20 or 30 per cent of the body surface. Individualization must therefore be an important feature of any plan of treatment. Close scrutiny of such cases will undoubtedly minimize the mortality. It is in this group of cases that special methods of treatment may be indicated. For example, the injection of sodium lactate or bicarbonate may prove to be of decisive importance (5,13,14). In subsequent patients with such severe manifestations we expect to study changes in the carbon dioxide combining power and the effect of introducing bicarbonate or lactate solutions. The preference for whole blood over plasma (1,9,14) even though hemoconcentration is present may also prove decisive in this group of patients. It would seem obvious, however, that no method of therapy can be evaluated when used in extensive burns which would have done just as well without them.

With special emphasis on these potentially fatal cases which we believe can be detected shortly after admission, routine care of severe burns need not involve complicated methods of treatment. This is an important practical consideration. If the routine case can be handled in a relatively simple manner, attention and effort can be more effectively concentrated on the more serious ones in order to answer some of the unsolved questions, particularly regarding methods of therapy designed to further reduce mortality.

SUMMARY

A series of 55 severe burns (covering 10 per cent or more of the body surface) were treated by the application of a simple gauze dressing, without preliminary débridement, but with meticulous aseptic care, and left in place as long as possible, often 2 weeks. Plasma transfusions were not used as routine, but only when indicated by circulatory impairment; as part of the early treatment it was employed in 10 of the 43 healed cases. Morphine was not used as routine, but only for the relief of pain in 9 of the 55 cases. A high fluid and food intake was an essential feature of therapy and was possible from the beginning by the oral route in all but a few of the severe cases. The clinical findings in the 43 healed cases were satisfactory and showed relative absence of infection, rapid healing, and required a relatively small amount of skin grafting.

Analysis of the systemic manifestations shows tremendous variation and suggests that the extent or depth of the skin involved is not always an accurate indication of its seriousness. Of great significance was the kind of burn, which should be described as flame or scald, and, when possible, in terms of the duration and temperature of the burn stimulus. Analysis of the fatal cases suggests that they may be detected early by the presence of vomiting, shock, toxemia. In the face of such manifestations even in nonextensive burns special therapy is indicated to reduce mortality further in these cases.

TECHNIQUE FOR THE REPAIR OF POSTOPERATIVE ABDOMINAL HERNIAS

NEIL JOHN MACLEAN, M.D., M.R.C.S. (Eng.), F.A.C.S., F.R.C.S. (Can.),
Winnipeg, Canada

IT is not my intention to discuss the prophylaxis of postoperative abdominal hernia. The purpose of this communication is to discuss the surgical technique for the closure of the ring or opening when a hernia has unfortunately developed.

ANATOMICAL CONSIDERATIONS

For the purpose of this discussion the abdominal wall may be considered as divided into two parts, an upper and a lower, the level of the umbilicus being roughly the dividing line.

Thus a cross section of the abdominal wall at the various levels may be comparable to a bow with a taut string in the upper and to a bow with a loose string in the lower (Fig. 1A and B).

In the upper abdomen the wall is firm and tense and the strong lateral pull of the abdominal muscles and their costal attachments frequently make closure of vertical incisions difficult. Every surgeon has experienced the annoyance of the sutures cutting the tissues when closing the posterior sheath of the rectus muscle. When a hernia develops

in this region, paradoxical as it may seem, the long axis of the ring is pulled transversely though the primary incision was vertical (Fig. 2A).

In the lower abdomen the wall is more lax, tends to bulge forward and downward, and in some cases becomes attenuated and even pendulous. Here the hernial opening is usually longer in the vertical diameter (Fig. 2B).

The linea alba is normally weaker in the lower abdomen. When a pendulous abdomen develops, usually associated with an umbilical hernia, the linea alba gives way to a point about 2 inches above the symphysis pubis. Professor I.M. Thompson, head of the department of anatomy in the University of Manitoba, stated during a discussion of this fact that: "The structures that reinforce the linea alba at this location are the pyramidalis muscles and their fibrous attachments to the linea alba and the reflected parts of the inguinal ligaments. These fibrous attachments undoubtedly prevent any further downward diastasis of the rectus muscles."

Furthermore, the diastasis of the rectus muscles stops abruptly above, at, or near the level of the umbilicus and this is where the lowest pair of the transverse intersections (linea transversae) of the rectus muscles is attached to the linea alba on each side. Thus with the distention limited above and below and laterally by the rectus muscles, the internal ring of a pendulous abdomen is well defined. These anatomical limits may be disrupted when a pendulous abdomen results from an incisional hernia.

TECHNIQUE OF REPAIR

Taking into consideration the anatomy of the abdominal wall and the structural changes that occur, four methods seem applicable to the various types of hernias that follow abdominal operations.

Fig. 1 Diagrammatic illustration of muscular tension.
A, Upper wall. B, Lower abdominal wall

Fig. 2. Illustrating the shape of hernial ring resulting from muscular pull in A, the upper abdomen; B, the lower abdomen.

1. In the upper abdomen, the ring being longer in the transverse diameter, repair would logically be done transversely. This is applying the principle of the Mayo umbilical hernia operation to a postoperative hernia in this region. Arthur E. Benjamin has also applied this principle successfully in his work in suitable cases. I have frequently split the upper (usually the thicker) margin of the ring into two flaps and sewed the lower edge between them, thereby making stronger union (Fig. 3). As the posterior flap of the divided upper margin is necessarily sewed to the posterior surface of the lower there is less likelihood of omentum worming in between stitches as pointed out by Elliott Michelson and William Raffel.

2. In the lower abdomen the wall being more lax the problem of closure therefore is quite different. Here the hernial ring is a vertical oval and closure should be done vertically. The lateral margin of the ring, the

Fig. 3. In the upper abdomen repair is done transversely by overlapping the edges or splitting the upper and sewing the lower between the flaps formed.

thicker of the two, is split and the medial margin is stitched between these two lateral flaps, three layers thereby closing the opening (Fig. 4).

3. At times the hernial opening is very large, as if the whole incision had separated and neither transverse nor vertical sewing seem to suit the case, the tension in the center being too great. In this event I have found the following expedient useful. Sewing is begun at the lowest point of the ring or opening and is continued upward to a point where tension is not too great and the sutured part can meet with the upper segment of the ring (Fig. 5A). The remaining part of the opening is then closed transversely resulting in a "T" shaped suture line (Fig. 5B).

In rare instances this procedure may be reversed, sewing beginning at the uppermost point of the opening. Only once in a very high hernia, following a paramedian incision which had completely disrupted, I found this latter method to be the only one that seemed suitable in this particular case (Fig. 6B). Where

Fig. 4. Lower abdomen. A, Hernial defect. B, Lateral margin is split. C, Medial margin is sewed into the lateral cleft. The suture lines are not directly superimposed and they have a buffer layer between them.

Fig. 5. A large circular ring may be closed by a combination of A, left, vertical; B, transverse sewing.

Fig. 6. Closure of a large ring partly from below upward A, or from above downward; B, depending on the muscular pull and ending the closure transversely. Only in an exceptional case would the second procedure be applicable.

overlapping cannot be done, figure-of-eight reinforcing stitches are used. These stitches are tied over a Wetherbee plate as this plate assures no give and there is no drag on the skin. If the stitches are tied without tension cutting or necrosis of the fascial edges should not occur (Fig. 7). These stitches remain in 14 or more days.

I would like to point out here that dissecting out the anatomical layers which have become fused together from the primary operation, as some advocate, is inadvisable. To do so prolongs the operation, unnecessarily traumatizes tissue with poor circulation and furthermore suture material is necessarily superimposed one row upon another which does not favor good healing.

4. In long standing cases in the lower abdomen the wall may be, as already mentioned, attenuated or even pendulous, especially if

Fig. 7. Reinforcing figure-of-eight silk worm gut stitches tied to Wetherbee plates. The ends of two parallel stitches are tied together at one side of the plate and the opposite ends on the other side. The stitches do not pass over the skin wound or the plates. It is best to use double strand stitches.

the rectus muscles have become atrophied from the severing of nerves. For this type the three flap operation for the extreme pendulous abdomen that I described before this Association in 1917, seems best suited (3). The operation was originally designed for cases in which an umbilical hernia had piloted the protrusion so that the umbilicus (and its hernia) was no longer in its normal position in front of the abdomen but was 15 or 16 inches farther down

Fig. 8. Pendulous abdomen. A, Simple pendulous fat (panniculus adiposus). Note the abdominal wall is intact. B, The linea alba has gradually stretched into a funnel-like process. An umbilical hernia is at the apex, having descended far from its normal position. The funnel-like tubular process is filled with small intestine and omentum. Note: The defect does not reach the symphysis below and only to the normal umbilical level above. This is not a postoperative condition.

SURGERY, GYNECOLOGY AND OBSTETRICS

there is marked diastasis of the rectus muscles. This would necessarily apply to a hernia in the midline at or below the level of the umbilicus, but also it is applicable in hernias lateral to the midline where the ring is large and the wall thinned out and bulging.

The preoperative and postoperative treatment needs stressing. Preoperative preparation is directed toward (1) reducing distention, (2) reducing distention, (3) cleaning and sterilizing the operative field, and (4) treatment of avitaminosis and any secondary anemia. This preparation may in some cases take as long as 3 months.

The postoperative treatment consists of (1) flexion of abdominal muscles with pillows (not a straight back rest), (2) nasal gastric suction in all cases until the stage of distention is past and the early use of rectal tube and the judicious administration of prostigmine and pitressin, and (3) surgical fluids *per os* for 4 days or longer if necessary.

RÉSUMÉ

1. The type of operation for the repair of an incisional hernia varies for each case and

has little to do with the type of the primary incision.

2. The shape of the hernial ring will determine whether closure shall be vertical or transverse.

3. Dissecting out the individual primary layers is unnecessary and complicates the operation. Overlapping is preferable or splitting the thicker edge with overlapping and underlapping is to be preferred. The simpler the procedure the better.

4. A large hernial ring may be closed by combined vertical and transverse suturing as described.

5. In a huge hernia with attenuated and pendulous abdominal wall the "Three Flap Operation" will, I think, be found most suitable.

6. Meticulous preoperative and postoperative treatment and care are a *sine qua non*.

ONE STAGE TUBED ABDOMINAL FLAPS

Single Pedicle Tubes

DARREL T. SHAW, M.D., F.A.C.S., Major, M.C., A.U.S., Cleveland, Ohio, and
ROBERT L. PAYNE, Jr., M.D., Major, M.C., A.U.S., Norfolk, Virginia

WAR wounds of the upper extremity involving extensive loss of soft tissue frequently require pedicle replacement of skin and subcutaneous tissue. The need for early coverage and the desirability of expediting the treatment of a large number of cases has emphasized the usefulness of the direct abdominal flap for this purpose. Single pedicle abdominal flaps may be applied to any defect of the hand or forearm as a one stage procedure. The open pedicle flap as frequently used has the disadvantage of a contaminated wound requiring secondary closure. Any open wound of the hand impairs the return of function. Therefore, it is desirable to convert the donor area and base of the pedicle into a closed wound. This also diminishes the dressing problem and the possibility of infection at the time of division. The donor site may be sutured primarily or covered by a split thickness skin graft. In either case the base of the pedicle may be grafted. Whenever possible, the authors have closed the donor site as a linear incision, a simpler and more direct method which minimizes the subsequent deformity. The desirability of closing the base of the pedicle as well as the donor site has led to an endeavor to combine the advantages of the closed tube with the advantages of the direct abdominal flap. This has been successfully done in 31 cases by constructing one stage tubes, 25 of which covered defects of the hand and wrist.

It is possible to raise large, long, oblique, or vertical flaps from the lower abdomen and still close the donor area because of the greater mobility of the tissues in this region. When based inferiorly an excellent blood supply is assured by including the superficial epigastric and superficial circumflex iliac veins and accompanying arteries. These characteristics

of size and viability permit easy tube formation. When combined with the adaptability of the hand to various positions, the usefulness of these tubes for covering irregular defects of the hand becomes apparent.

Single pedicle tubes, based inferiorly, including the superficial epigastric veins have been constructed, varying in length from 5 to 18 centimeters and varying in width from 3 to 7 centimeters. Exact limitations of size have not been determined. The dimensions depend on the size of the defect to be covered and on the obesity and mobility of the abdominal tissues. The superficial veins can usually be seen through the skin and are used

Fig. 1. Infra-red photograph showing superficial epigastric veins (left), and donor area where tube was recently detached (right).

Fig. 2. Diagram of tube construction showing inclusion of superficial epigastric veins, undermining of margins for closure of donor area, and closure by continuous subcuticular stainless steel wire suture.

as a guide in outlining the flap. If the veins are not visible their approximate location can be estimated.

The flap is outlined on the abdomen as two parallel incisions tapering to a blunt point superiorly. It is raised either just superficial to Scarpa's fascia or may include the fascia. The margins of the donor defect are undermined for closure in the fatty areolar layer beneath the fascia. Additional relaxation may be obtained by incision of the fascia parallel to the skin margins. The attachment of the flap is extensively undermined to allow mobility in closing the angles when the base of the tube is formed. The donor defect is closed with

continuous subcuticular stainless steel wire. This procedure has proved to be a rapid, simple, and satisfactory method of closure and incorporates the basic principle of using a buried subcuticular suture for closing skin under tension. This continuous suture includes one or both angles of the incisions at the base of the flap and begins formation of the tube. By staggering the inferior ends of the incisions the base of the tube may be rotated through an arc of 180 degrees. If the medial incision is shorter the open surface of the tube will rotate laterally. If the lateral incision is shorter the tube will be rotated medially. The angle of rotation depends on

Fig. 3. Diagram showing rotation of tube to right or left, by staggering of incisions.

the amount of staggering of the original incisions and on the width of the flap. Thus the open surface of the tube may face medially, superiorly, or laterally, without twisting the tube itself. Combined with the fact that it may be folded on itself, application to the hand is permitted in a wide variety of positions.

The flap is formed into a tube by simple interrupted sutures and is applied to the recipient defect by subcuticular sutures of fine, white, twisted nylon and interrupted skin sutures of fine stainless steel wire or fine silk. The wire seems to give less reaction than does silk in the presence of moisture.

If the original defect is completely covered at the time of application, the tube may be handled much the same as is an abdominal flap and divided in about 3 weeks. However, if the tube itself is used to cover a portion of the defect, a longer period of time is allowed and some type of delay is advisable, depending upon the length of the tube. When the tube has a small application to the recipient area, as when it is attached to the wrist to be carried to some other portion of the body, or used in total thumb reconstruction, the time of application must be longer than when a double pedicle tube that has been constructed previously is applied. This difference in time we attribute

to the primary healing reaction and unestablished blood supply in the one stage tube. Compared with the double pedicle tube the time of application is longer but the total time is shortened.

Delaying tubes, which not infrequently have a border line blood supply, is best done as a closed procedure in order to prevent superimposed infection which may further impair the blood supply, in this manner forming a vicious cycle which may result in partial loss of the tube.

SUMMARY

One stage single pedicle abdominal tubes have been found a practicable and an advantageous method of applying skin and subcutaneous tissue to defects of the hand. They combine the speed of the abdominal flap with the cleanliness of the tube. When attached to the wrist they may be carried to other parts of the body.

THE EFFECTS OF CERTAIN DRUGS ON THE SPHINCTER OF ODDI

NORMAN W. THIESSEN, M.D., F.A.C.S., Lakewood, Ohio

PRESSURE changes in the biliary system secondary to variations in tone and states of contraction of the musculature surrounding the lower end of the common bile duct have been shown to occur in many animals and in man. Former investigations have demonstrated changes in intraductal pressure by measuring these variations, which have been relayed up through a cannula in the common duct and into a manometer system. Since direct observations of the sphincteric contractions of this muscle system had not been recorded, it was believed that their measurement might throw additional light on the reactivity of the sphincter of Oddi.

LITERATURE

Oddi was the first to measure the intraductal pressure. He measured the tonus of the sphincter by observing the height of a column of water supported in a tube tied in the common duct. Doyon reversed this procedure by measuring the amount of fluid passing through the ampulla from a specially constructed manometer connected with the common duct.

The effects of external stimuli and diet on intrabiliary pressure have been studied by several observers. Archibald noted that touching the duodenal mucosa with hydrochloric acid or pinching it raised the tone of the sphincter so that pressures as high as 800 millimeters of water were recorded. McWhorter found that magnesium sulfate in the duodenum lowered the pressure produced by the tone of the sphincter from 50 to 100 millimeters of water. Jacobson and Gydesen observed that in addition to magnesium sulfate, acids and peptone lowered the sphincter tone. Cole found that isolated gastric contents influence the pressure variably. Bruno, Klodnicki, Boldyreff, and Rost observed in-

termittent gushes of bile from the ampulla of unanesthetized dogs which they interpreted to be the result of the relaxation of the sphincter. This observation has been confirmed many times by others (Puestow; Klee and Kluepfel).

Lueth studied the effects of various drugs on the intraductal resistance in the common duct and found that in general the effects on the intraductal resistance and duodenal tone were similar.

The pressure necessary to cause a flow of water from the common duct through the ampulla has been measured by many observers. In the dog it has varied from 60 (Winkelstein and Aschner) to 675 (Oddi) millimeters of water. In man most observers agree that the normal tonicity of the sphincter of Oddi varies between 90 and 150 millimeters of water (Butsch, McGowan, Walters; and Elman and McMaster, 9, 10). This resistance may be raised from 600 to 700 millimeters water under certain circumstances.

METHOD

External biliary fistulas were prepared in dogs according to Puestow's technique. The major ampulla was transplanted to the skin after intestinal continuity was restored. The first operation consisted in an anastomosis such as is carried out in a posterior Polya resection of the stomach. When the dog had recovered, the closed duodenal loop was transplanted between the abdominal muscles and the skin. At the final operation, 7 to 10 days later, this loop was opened and cut across between the openings of the pancreatic and common bile ducts. The lower opening into the bowel was inverted and the skin closed over it. The edges of the upper opening were attached to the skin so that the ampulla was easily accessible. Over a period of months it was necessary to raise this portion as it tended to retract into the abdominal cavity.

From the Laboratory of Surgical Research, Western Reserve University, Cleveland, Ohio.

The dogs were fed on a standard diet with cereal and meat scraps. On this standard regimen they were kept alive for months. The two dogs on whom most of the readings were made stayed alive 215 and 250 days, respectively. The most dangerous complication exclusive of distemper was the opening of the lower loop, causing complete loss of pancreatic secretion, maceration of the skin, and a rapid downhill course. These dogs were thus kept alive with complete loss of bile except what they licked from the fistula. The mucosa around the fistula on manipulation bled easily, but only one dog showed any evidence of gross bleeding at autopsy.

After complete recovery the dog was strapped on his back on a table four or five times weekly for a half hour until he learned to lie quietly. All readings were made in the fasting stage. A small latex rubber bag with a hard tip and measuring 3 millimeters in diameter was inserted through the ampulla for a distance of about 2 centimeters. The proximal end was attached by glass and rubber tubing to the recording device. At first this method consisted of a rubber tambour and the conventional writing point on a smoked drum. The recorded excursions were so small that a more sensitive method which would increase the deviations was sought.

A photoelectric method by means of the electrocardiographic apparatus was devised. A beam of light separate from the electrocardiograph was reflected from a projection cell onto the photographic paper. Any variations in pressure on the rubber bag were transmitted to the cell, thus causing deflections of the light beam. A closed air system was used throughout the experiments. Since the speed of the photographic paper past the exposure slit was slowed by adding resistance in the electric circuit controlling the motion, variations in this speed were noted, caused by

Fig. 1. First record, control reading; second record, following inhalations of amyl nitrite for 1 minute; third record, 5 minutes later.

changes in electrical resistance and friction of the rotating belt. To make the results comparable a timing device was added. A metronome was placed in front of the beam of light used in normal electrocardiography so that the moving pendulum would cut the beam. Because of the construction of the electrocardiograph the metronome could not be put exactly in front of the light beam, with the result that two vertical white lines close together caused by the metronome pendulum cut the light beam at the end of one and at the beginning of the next arc. Accordingly, the time interval between any comparable two lines is two seconds, the metronome being set at 60 oscillations per minute.

The curves shown on the photographic paper are the recorded contractions. The direction of the contractions is denoted by the arrow. The horizontal white line is the baseline used in electrocardiography and has no relation to the present records. No attempt for a standard baseline was made, since a "normal" or basal reading was taken at each period of observation for 10 to 15 minutes before any stimulus was used. Various stimuli

Fig. 4. Record taken during excitement.

Calcium. The dog was given 10 cubic centimeters of 5 per cent calcium chloride intravenously after a control reading was taken. There occurred a slight increase in tone, with no change in the amplitude of the contractions, and no change in the number of contractions.

Houssay and Rubio have stated that calcium chloride caused contraction of the gall bladder. Erbsen and Damm report that the calcium ion causes relaxation of the isolated guinea pig's gall bladder. The action of calcium on isolated smooth muscle is variable, although in the main it tends to cause relaxation. The results obtained here indicate that calcium increases the tone of the smooth muscle surrounding the lower end of the common bile duct.

Novocain. The topical application of 5 per cent novocain to the exposed ampulla had no observable effect on the tone, amplitude, or number of contractions.

Adrenalin. A subcutaneous injection of 1 cubic centimeter of 1:1000 solution of adrenalin caused an increase as high as 4 millimeters in the amplitude of the contractions, but no change in the tone or number of contractions. A dose of 2 cubic centimeters caused a still greater increase in the amplitude of the contractions to as high as 8 millimeters, an increase in the respiratory rate, and some restlessness in the animal.

Lueth reported a decreased duodenal pressure and intramural resistance after giving 1 to 5 cubic centimeters of 1:1000 epinephrine. With smaller doses the effects were inconsistent. In small doses the action on the gall bladder has been reported as variable. Larger doses caused contraction of the gall bladder. The amounts given in the present experiments were large, the effect being in proportion to the quantity of drug given.

Amyl nitrite. The dogs were caused to inhale the fumes of amyl nitrite for 1 minute.

were used. Observations were limited to one a day so the effects of one stimulus would be gone when another was given. The stimulus was administered, an immediate reading taken, and a final reading again at 5 minutes. Repeat observations on the same animal under the same conditions were made as control procedures. The resulting curves were recorded, the paper was developed, dried, and representative portions were mounted on cardboard.

A standardization of the contractions showed that a difference of 1 millimeter on the recording paper equals 2 centimeters of water pressure.

OBSERVATIONS

Normal. A comparison of the control readings, i.e., those taken before any drug was given, shows that a slight rhythmic contraction occurs every 2 to 6 seconds. Each contraction was slow, taking from 1 to 2 seconds for the full variation in pressure to be recorded. These variations ranged from 2 to 7 millimeters, the average being 3 millimeters. During vomiting the pressure increased in one instance 12 millimeters or 24 centimeters of water pressure. This same change in pressure occurred in a much slower rhythm during excitement.

It is interesting that the "normal" or control readings vary from day to day in tone, rhythmicity, and number of contractions.

The only effect on the state of the muscle tested was a slight decrease in tone (Fig. 1).

The effect of nitrites on smooth muscle is definitely one of relaxation. It is interesting, therefore, that while the tone of the muscle was reduced, the amplitude and number of contractions were unaffected. In view of the clinical relief which was obtained in patients with biliary dyskinesia, this finding was to be expected.

Hydrochloric acid. Tenth normal hydrochloric acid was applied topically to the ampulla as it lay exposed. The slight decrease in tone which occurred disappeared in one set of experiments and almost disappeared in the other during the observation period of 5 minutes. In one experiment the amplitude of the contractions increased slightly. Puestow noted a fairly constant stimulating effect on duodenal contractions and occasionally small spurts of bile occurred when dilute hydrochloric acid was applied. Elman and McMaster (9) noted a marked decrease in intraductal pressure when acid was introduced into the duodenum, while alkali caused a similar increase.

Morphine sulfate. One-sixth grain morphine sulfate was administered to the animal hypodermically. The frequency of the contractions increased slightly. The amplitude of each contraction increased from 3 to 6 millimeters, while a negligible change in tone occurred (Fig. 2).

Since morphine causes vomiting in dogs, several records during this action were taken. The musculature would relax until the actual vomiting occurred, when a sudden spasm would occur. Relaxation followed immediately. The time required for this was from $\frac{3}{5}$ to 1 second. The pressure increased as much as 12 millimeters or 24 centimeters of water. No protracted spasm as reported by Butsch, McGowan, and Walters was noted. How much of this contraction was due to duodenal muscles could not be determined.

Piluitrin. One cubic centimeter of surgical pituitrin was injected hypodermically (Fig. 3). A definite and marked decrease in muscular tone occurred. The amplitude of the contractions increased up to 15 millimeters, while the number of contractions remained

about the same. The record also shows many smaller contractions occurring, about 6 to 8 per minute. These could not have been the effect of respiration, because the respiratory rate at the time was between 30 to 40 per minute. In comparison to the normal tonus rhythm they could be described as fibrillary contractions. They occur in some of the other records in a less marked variation and may be artifacts.

The decrease in tone agrees with the findings of Lueth, who found an initial decrease in intramural resistance followed by a slow return to the control level.

COMMENT

The intraductal pressure at the level of the sphincter is an aggregate of four components. These consist of the secretory pressure from the liver, the pressure dependent on the state of the musculature of the gall-bladder wall, the compression exerted by the muscle bundles, both circular and longitudinal, surrounding the lower end of the common duct, and the back pressure exerted from the lumen of the duodenum when the ampulla is patent. In the experimental set-up which is here reported, all except the compression factor of the sphincter and duodenal muscles have been eliminated.

In the operative procedure used in these experiments the circular muscles of the duodenum have been cut so that any remaining constricting action is a purely local contraction. The recorded differences then are caused more probably by the action of the sphincter, and the large changes in pressures reported by other observers have been due to the combined action of the duodenal musculature and the sphincter.

The greatest variation from the control pressure was 7 millimeters and the greatest variation under any circumstances recorded was only 15 millimeters, or about 30 centimeters of water pressure, as computed by standardization procedures. After similar operative procedures and cholecystectomy, Puestow reported 20 to 30 centimeters of bile pressure in the common duct. Ivy states that in the unanesthetized fasting dog the intramural resistance may vary from 9 to 25 centi-

meters of water pressure, depending on the length of the fast. This variation coincides with the present finding. These low pressures may have been the result of several things.

There is little doubt that most, if not all, of the vagal fibers were divided during the operative procedures. The sympathetic nerves around the hepatic artery remained intact, however. Since the exposed duodenal segment seemed to recover a normal tone, the ultimate effect of division of the vagus seems questionable. Under barbital anesthesia, stimulation of the peripheral end of the cut right vagus nerve in the neck caused an increase of 4 centimeters of water pressure. Stimulation of the central end of the right vagus and both ends of the severed left vagus had no effect upon the contractions of the sphincter.

In addition to the nerve section, the insertion of the bag through the ampulla may have partially paralyzed or fatigued the sphincter, so that complete recovery had not occurred before the period of recorded observations. If this is true, then the pressure differences recorded are only a fraction of the real changes which occurred.

The length of observation was usually about 30 minutes. In certain experiments there is suggestive evidence that the effects of the drugs became apparent only after the 5 minute interval. However, readings continued beyond this period became complicated by restlessness on the part of the dog, so that the criticism of possible incomplete observation must be accepted (Fig. 4).

In acute experiments with the ampulla raised to the skin and using the same pressure recording apparatus, a normal tone of 0.5 centimeter of water was found. This was a maintained pressure in spite of the barbital anesthesia. This procedure was not done on the unanesthetized dogs, but it seems reasonable to assume that the normal tone in those animals would be higher. Lueth found the pressure necessary to open the sphincter to vary from 3 to 5 centimeters of water, which is probably normal tonic resistance.

SUMMARY

In dogs with a biliary fistula preparation which excluded all pressure factors except

that which could be ascribed to the action of the sphincter of Oddi, studies of the changes in pressure in response to various drugs were carried out. The animals survived for many months (1 for 250 days) under normal conditions, so that observations could be carried out uncomplicated by anesthesia or trauma. In the fasting animal the bile flowed only rarely and the exposed segment of bowel was quiet. The sphincter normally underwent a more or less rhythmical slow contraction every 2 to 6 seconds, showing a pressure variation of 4 to 14 centimeters of water. The definite changes observed may be summarized as follows:

Calcium chloride administered intravenously caused a slight increase in tone.

Hypodermic adrenalin chloride, 1:1000 increased the amplitude of the contractions.

Topical 5 per cent novocain showed no effect.

Inhalations of amyl nitrite resulted in a slight decrease in tone.

Tenth normal hydrochloric acid applied topically caused a slight transient decrease in tone.

Morphine sulfate given hypodermically increased the number and amplitude of the contractions. A marked increase in amplitude occurred during the act of vomiting. This is interpreted as a defense mechanism against reflux of duodenal contents into the biliary system.

Surgical pituitrin hypodermically caused a marked decrease in tone and a marked increase in the amplitude of the contractions.

These results in pressure changes are comparable, though in decreased values, to those reported obtained by methods of cannulating the common duct. Because of the method here reported, it is believed that these pressures more nearly represent the action of the sphincter of Oddi.

LIPOSARCOMA OF THE FEMALE MAMMARY GLAND

ARTHUR PURDY STOUT, M.D., and MAX BERNANKE, M.D., New York, New York

LIPOSARCOMA of the mammary gland is a rare tumor form in this organ, and the few cases which have been reported contain sparse and conflicting information about its degree of malignancy. Some of the metastases and causing death while others have pursued a much less noxious course. It is therefore by no means simple to decide how to treat liposarcoma of the breast when confronted with one. Because of this we propose to present the evidence of previously recorded cases, describe a new case, and discuss the question of treatment.

In Geschickter's monograph on diseases of the breast, mention is made without details of 3 women between the ages of 52 and 65 years, each of whom had rapidly growing breast tumors measuring 8 centimeters or more in diameter. All progressed rapidly to a fatal termination. He states that they can metastasize to the lymph nodes and that they are radiosensitive but not easily cured by this form of treatment. This exceedingly gloomy picture is duplicated by Lifvendahl's case. This was a 41 year old woman who noted small masses in both breasts. Three months later when she was examined there were 10 nodules in the left and 15 in the right breast. Bilateral mastectomy was done. The nodules were grayish-white and slimy. The largest measured 5 by 4 by 6 centimeters. Three months later she died with evidence of pulmonary metastases. It was an undifferentiated mucoid liposarcoma with many bizarre lipoblasts.

Adair and Hermann cite briefly 4 cases from the Memorial Hospital, New York. Three of them were called myxoliposarcomas of low grade malignancy. One of these had numerous recurrences following simple mastectomy during a 10 year period and ultimately died of pulmonary metastases. Of the other 2 patients, one had local excision, the other radical mastectomy, and both remained free of disease respectively 4 and 4½ years after operation. The fourth patient was said to have had a "grade 4 liposarcoma" and lymphatic leucemia. She had no evidence of sarcoma 4 months after radical mastectomy. Other cases have not pursued such a malignant course. Delage and Massabiau described a 52

year old woman who had a breast tumor weighing 1700 grams removed. It was called a myxolipoma. Six years later there was a recurrent nodule below the scar. Ten years after the first operation there were 5 nodules in the breast which the patient said felt like a bag full of oranges. A mastectomy was done and the tumors again called myxolipoma. Deaver and McFarland believe that this in fact is a case of liposarcoma and we agree with them. Neumann's patient was 60 years old. She had a slimy tumor in the inner hemisphere of the left breast. It was excised but recurred and 1 year later the new tumor was cut out. Recurrence followed and the third excision was done after 10 more months. It was a myxoid tumor with many cells containing fat droplets. In its last manifestation it was as large as an apple and reached but did not invade the corium. Neumann called it a myxoma lipomatodes but it seems proper to consider this also a liposarcoma of the myxoid type. Merkel's patient was 26 years old. She had a tumor at the margin of the gland which extended outside of it and in 6 months reached a size of 9 by 5.5 by 3.5 centimeters. It was encapsulated and had foam cells in it some of which were of giant size. Merkel called it a pseudolipoma but Borst saw the sections and considered it a true lipoblastic sarcoma. The final result is not recorded.

Fox's patient was 58 years old when a complete mastectomy was done because of an encapsulated tumor in the breast which had been present for 2 months. No metastases were found in the nodes and the patient was well 5 months later. It was called a liposarcoma but no other details are given. Cheate and Cutler also record the presence of a small liposarcoma in the female breast which looked like embryonal fat. The photomicrograph shows many rounded foam cells, some with large bizarre nuclei. No other details were recorded.

There are 2 other cases in the literature which seem to be examples of liposarcoma developing in the stroma of cystosarcoma phyllodes or adenofibrosarcoma. In Binkert's case a man's head sized tumor, weighing 3 kilos, grew in the left breast of a 39 year old woman in less than a year. A radical operation was done and axillary metastases were found. In 5 months there was a recurrence in the scar and metastases in the opposite

From the Laboratory of Surgical Pathology, Columbia University, and the West Side Hospital, New York.

Fig. 1. Liposarcoma of the breast. Photomicrograph of the margin of the tumor showing infiltration around sclerosed ducts and acini.

Fig. 2. Liposarcoma of the breast. Detail photomicrograph showing myxoid stroma and bizarre giant cells. Some of the cells are vacuolated.

axilla. A right radical mastectomy was done with removal of the nodule in the left-sided scar. The primary tumor was an adenofibrosarcoma (i.e. cystosarcoma phyllodes) with liposarcomatous stroma in places. The recurrence and metastases were liposarcomas with many bizarre giant cells but without epithelial elements. Binkert called the tumor a "fibrolipoadenoma intracanalicular sarkomatodes xanthomatodes mammae."

A case somewhat resembling Binkert's has been reported by Hinterberger. A 25 year old girl noticed a cherry sized tumor in her right breast which in a year attained the size of an orange. It was excised and during the next 6 years, 5 more operations for the removal of recurrences were carried out. The earlier tumors were fibroadenomas with sarcoma-like stroma. In the fifth specimen there was lipoblastic tissue between the recurrent sarcoma phyllodes nodules. The tissue from the last operation was studied in detail by Hinterberger. Now there was still a cystosarcoma phyllodes nodule but other nodules were lipoblastic tissue which invaded the surrounding mammary tissue. There were never any metastases observed. The final result is not reported.

It is of passing interest to note that liposarcomas have been described in the mammary glands of cats, dogs and guinea-pigs (Corsy and Thomas, Schultz-Brauns; lit.)

CASE REPORT

A married Jewess, aged 43 years, noticed a lump in the left breast on December 5, 1945. She consulted one of us (M.B.) about it the next day. Menstruation had been regular and the past history uneventful. Examination

showed a freely movable tumor 2.5 by 1.7 centimeters in the upper outer quadrant of the left breast. It was not attached to the skin and the axillary nodes did not feel enlarged. Roentgenograms of the chest and skeleton were negative. Sedimentation rate, Wassermann, and blood smears were normal.

Operation by one of us (M.B.) at the West Side Hospital on December 8, 1945, consisted of wide excision of the tumor and surrounding breast tissue. The wound healed well and there was no evidence of recurrence 2 months after operation. Gross examination of the specimen showed a mass of breast tissue 5 by 3 centimeters. Embedded in the center of this was a localized circumscribed tumor measuring 10 by 12 millimeters. It was soft, fleshy, and light brown in color.

Microscopic examination showed a tumor made up of a conglomeration of cells of varying size and shape, including round, spindle, and stellate forms and a number of bizarre multinucleated giant cells. These were set in a fibrous stroma some of the fibers of which were thick and others extremely delicate producing a myxoid appearance, although the mucicarmine stain showed no pink or red color. A scharlach R stain showed lipid droplets in some of the cells. The tumor was circumscribed but at its periphery invaded the surrounding breast tissue to a limited extent (Figs. 1 and 2). The tumor was considered a partly differentiated myxoid liposarcoma.

It is apparent from a study of reported cases that liposarcoma of the breast is a tumor which sometimes behaves in a most malignant fashion, metastasizing both through the lymphatic and blood streams and resulting in death. In other cases the infiltrative nature of the tumor is shown by repeated local recurrences after incomplete excision occasionally with a long free interval between excision and reappearance but without any metastasis, and finally there are cases apparently cured by adequate simple excision of tumor and surrounding breast tissue.

A study of a considerable number of liposarcomas led one of us (A.P.S.) to the conclusion that they could be divided into two main classes, those which show a considerable degree of differentiation and which do not metastasize as long as the whole tumor maintains its good differentiation and a second larger class which is poorly differentiated, may show various types of metaplasia, and which metastasizes in about 40 per cent of cases. A reasonable form of treatment for the first group was considered generous excision, because even if this was followed by recurrence, metastasis need not be expected; whereas in the second group, a more radical procedure should be carried out because of the potential danger of metastasis.

The case here reported was unusual because it was small and was generously excised within a few days of its discovery. It was felt that it could be placed in the more differentiated group and that therefore metastasis was extremely unlikely and that if local recurrence should occur after the generous excision of tumor and surrounding breast tissue, it would still be possible to do a mastectomy at a later date without jeopardizing the woman's ultimate chance of cure. For these reasons no further operative procedures were carried out. Had the liposarcoma belonged to the poorly differentiated group of liposarcomas, a radical mastectomy would have been the proper

treatment since such tumors may metastasize both through the blood and the lymphatic vessels.

SUMMARY

A new case of liposarcoma of the breast is recorded, previously reported cases are analyzed, and the treatment of this rare mammary tumor form is discussed.

DEFORMATIONS OF THE SKULL IN HEAD INJURY STUDIED BY THE "STRESSCOAT" TECHNIQUE, QUANTITATIVE DETERMINATIONS

E. S. GURDJIAN, M.D., F.A.C.S., and H. R. LISSNER, M.S., Detroit, Michigan

DEFORMATION of the skull due to hammer blows has been studied by the "stresscoat" technique (3). If the tensile deformations are of sufficient magnitude they cause cracks in a strain-sensitive brittle coating previously applied to the surface of the skull. The resultant deformation patterns may then be studied in the immediate vicinity of, as well as remote from, the region of the blow. "Stresscoat" (1,2) is the trade name of a brittle lacquer method of strain determination in any material subjected to static and dynamic loads. The surface of the structure is coated with a lacquer. Cracks form in this coating when the material to be tested is subjected to tensile strains of 0.0005 to 0.0015 inch per inch. The sensitivity of the lacquer depends upon the temperature and humidity conditions at the time of the tests. Different lacquers are used for varying temperature and humidity conditions. Before a test, the sensitivity of a given lacquer is determined by a calibrating device.

Dogs and monkeys were used in order to establish a correlation between the strain patterns obtained in the skull of the living animal under nembutal anesthesia, the skull of the dead animal with intracranial contents undisturbed and in the dry skull of the same animal (3). It was found that the patterns obtained in the dry skull were less extensive than in the skull of the dead animal or in the animal under anesthesia, but the direction and general distribution of the strain paths were the same in all 3 classes. It was justifiably concluded that the patterns obtained following hammer blows on the dry skull were similar to the findings in the living skull.

In the study of strain patterns in the human, dry and cadaver skulls were used. The effects of hammer blows on the midoccipital region near the parietal occipital suture, the midfrontal region, the anterior vertex at the midline, the lateral frontal, and the lateral posterior parietal regions

were studied (3). Following midfrontal blows, the strain paths extended toward the roof of the orbit, along the orbital rim, and toward the frontosphenoidotemporal junction at either side. With a midoccipital blow there were evidences of extensive deformation about the foramen magnum. Lateral frontal and lateral posterior parietal blows caused cracks in the lacquer extending toward the temple; with the former the direction of the cracks was downward and posteriorly, and with the latter downward and anteriorly.

It was found that the human and lower forms differed materially in their strain patterns. In the human the deformations detected by this technique were more localized. However, the value of the experimental animal in establishing correlation of results in the animal under anesthesia, in the skull of the dead animal with contents intact, and in its dry skull, was of inestimable value. It could be definitely stated that the patterns ob-

Fig. 1. This figure illustrates the method used for delivering known quantities of energy in certain locations in the skull. Before each experiment the skull is carefully weighed. It is then held at the proper distance from the steel plate to produce the desired energy at impact. The thread holding the skull is burnt with a match and following the impact the skull is caught on the rebound in order to avoid the possibility of secondary patterns from more bounces.

Fig. 2. The effect of 14.3 inch pounds of energy on the mid forehead. Upper left is skull G with sensitivity of lacquer at 0.00105 inch per inch. Upper right is skull C with sensitivity of lacquer at 0.00095. Lower left is skull B with sensitivity of lacquer at 0.00095. Lower right is skull D with sensitivity of lacquer at 0.00095. Note that there are minimal deformation patterns in each instance with the exception of skull B which shows no effects from the blow.

tained in the dry skulls were essentially the same as in living animals under anesthesia. This does not signify that the magnitude of the strains is the same, but that the strain paths are similar. It was also deduced with reason that the effect of the

skin and muscles on the strain pattern is negligible.

In the present paper certain quantitative data are given. The effects of a given amount of absorbed energy in various portions of the skull are

Fig. 3. Anterior vertex (midline) blow showing lines of strain extending toward the temple on both sides. This is skull B with sensitivity of lacquer at 0.00105 and with a blow of 14.3 inch pounds of energy.

described. Deformations resulting from blows of varying energy are also discussed.

PROCEDURE

Previous tests have shown that suture lines in dry skulls tend to interrupt the propagation of the cracks in the "stresscoat" lacquer. It was therefore decided to keep the skulls moist by immersing in normal saline solution between tests to prevent the disintegration of the tissue at the suture lines. One skull was permitted to remain dry as the tests progressed to determine any changes in deformation patterns resulting from the drying of the skull. Six human skulls, freshly obtained from the anatomical laboratories, and dissected free of soft tissues were used. Five were kept in normal saline solution, except when in use for strain determinations.

The skulls were removed from the saline solution in which they were stored several hours before coating in order to permit the excess moisture to drain off and evaporate. Just prior to spraying they were washed with ether. In no case was there any difficulty in getting the lacquer to ad-

here properly to the bone. The skull was first sprayed with a thin uniform undercoating of aluminum lacquer and after 15 minutes of drying a uniform coating of "stresscoat" lacquer was applied with a sprayer. Numerous calibration strips were coated at the same time. The lacquer was allowed to dry for 24 hours before a blow was administered.

In order that the results of tests made at different times could be correlated it was necessary to have the strain sensitivity of the lacquer within certain limits for all experiments. The range chosen was 0.00100 ± 0.00005 inch per inch of strain to produce cracks in the lacquer. When the test was about to be made, one of the calibration strips was tried to check the strain sensitivity of the lacquer for the existing temperature and humidity condition of the room. If the sensitivity was too great, the room temperature was increased until a calibration strip test showed that the sensitivity was 0.00100 ± 0.00005 . The skulls were then tested. A room with constant temperature and humidity condition would obviate some of the above described operations. However, with

Fig. 4. Anterior vertex (midline) blow in skull E with sensitivity of lacquer at 0.00105 and a blow of 14.3 inch pounds. Note that the pattern in this skull is somewhat more extensive than in skull B, Fig. 3.

the use of the calibration strips an accurate and quantitative determination can be obtained.

The skulls weighed from 1.07 to 2.23 pounds. They were dropped on to a polished steel block weighing several hundred pounds. Therefore the energy absorbed by the steel block was negligible. The amount of energy absorbed by each skull was determined by its weight and the distance through which it was dropped. The velocities at the instant of impact varied from 5.4 to 9.9 feet per second. Each skull was supported so that the blow was delivered perpendicular to a plane tangent to the point of impact.

A series of tests were made on the six human skulls with blows delivered to the midfrontal, midoccipital, lateral frontal, lateral posterior parietal, and anterior vertex (midline) regions. The skulls were suspended above the steel block with thread. For occipital blows the thread was tied to the bridge of the nose; for frontal blows, to a hook in the foramen magnum; for lateral posterior parietal blows, it was tied to the zygomatic arch; for vertex blows, the skull was supported by a thread tied to a book in the foramen magnum, and for the lateral frontal blow it was supported

from a thread in the posterior parietal region tied to another tightly encircling the skull. The skull was then adjusted to the correct height above the steel block. The thread was burned, allowing the skull to drop on the steel block and it was caught on the rebound to prevent the formation of secondary strain lines in the lacquer due to additional bounces (Fig. 1).

The strain lines were next developed by coating the lacquered skull with red dye etchant. The excess etchant was removed with an emulsifier solution, leaving the dye only in the cracks. For purposes of photography each crack was then outlined with India ink. Faint cracks were gone over more lightly than heavy cracks which were stained with heavy lines of ink.

The formation of cracks in the lacquer indicated a minimum tensile strain of 0.00100 ± 0.00005 inch per inch. The magnitude of the strain in certain portions of the area of cracks may be considerably in excess of the value given above. For instance, in the region of a strain pattern the cracks are closely spaced at the center and more widely spaced toward the periphery. It is evident that a strain gradient exists with the strain of the

peripheral cracks being about 0.00100 inch per inch and increasing in magnitude toward the more closely packed cracks in the center.

In a series of experiments the same amount of energy (14.3 inch pounds) was used in different locations of the skull. Another group of experiments were carried out in which the quantity of energy applied to different regions was varied from 8 to 24 inch pounds (Table I).

EXPERIMENTAL DATA

In Table I the weight of each skull at the time of a given test is tabulated. Skull B was kept dry and the other 5 were immersed in normal saline solution between tests. Only skull C shows a marked change in weight. This was caused by the separation of a portion of the intracranial contents which remained attached to the internal surface of the skull during the first two tests. It should also be noted that in certain experiments the skull weight was higher than in certain previous tests. This is almost wholly due to the varying amount of aluminum and lacquer coating sprayed upon the skull. Both are heavy and can cause differences in weight depending upon the thickness of the layer applied to the surface of the skull. The strain patterns in the skull not immersed in saline (skull B) were essentially of the same distribution and direction as those obtained from the moist skulls, but as the tests progressed a separation of the sutures gradually occurred and the results obtained after the sixth test were discarded. Such a separation not only may prevent the propagation of strain paths but it constitutes an area of energy absorption, causing quantitative errors in results. This is evident from the examination of the strain patterns obtained with 14.3 and 20 inch pounds of energy, Tests B-2 and B-8. In the case of this skull the strain cracks were less extensive for the higher energy than for the lesser value. It is felt that the most reliable results are obtained in fresh skulls which are kept moist in saline between tests. However, skull D, which was kept moist throughout the tests, had a separation of the lambdoid suture on the ninth test and was then discarded. The experimental data given were completed during a period of 3 months.

A constant energy of 14.3 inch pounds was used in all skulls in the first 6 experiments (Table I). Varying amounts of energy were used beginning with test 7. The findings will be described under (1) blows of constant energy, and (2) blows of varying energy.

Results with constant energy. The application of 14.3 inch pounds of energy by the above-described

Fig. 5. Lateral frontal blow in skull E with sensitivity of lacquer at 0.00105 and a blow of 14.3 inch pounds of energy.

procedure resulted in patterns of different magnitude in different locations. Following an occipital blow the deformations were more extensive. With the same amount of energy midfrontal blows resulted in very slight change. There was also some difference in magnitude of patterns obtained with blows at the same location but in different skulls. Such variations from skull to skull may be explained in part by differences in shape, contour, and thickness, and slight change in the location of the blow in successive tests. These data will be described in greater detail in the next few paragraphs.

Midfrontal blow with 14.3 inch pounds of energy. These experiments were carried out on 5 skulls kept in saline and 1 dry skull. In Figure 2 it is noted that minimal strain cracks are found in the frontal bones in 3 of 4 specimens. In 1 (skull B), a blow of 14.3 inch pounds of energy caused no cracks in the lacquer with a sensitivity of 0.00095.

Anterior vertex (midline) blow with 14.3 inch pounds of energy. A blow in the anterior vertex at

Fig. 6 Lateral frontal blow on the right side in skull B with 14.3 inch pounds of energy and sensitivity of lacquer at 0.00105. In this experiment the skull fractured with line of fracture extending from the orbital rim to the middle of the area of impact.

made satisfactory recoveries. If cholangitis and obstructive symptoms develop after a reconstruction operation, one would best defer further surgical treatment unless definite complete obstruction is proved, as nearly a half of the patients who were reported well 2 to 12 years after operation had experienced transient cholangitis and symptoms of obstruction at one time.

On the other hand surgical treatment should not be withheld from patients on the grounds of a poor risk, for these 188 patients who underwent 496 operations, 257 elsewhere, underwent 188 procedures with only a 12 per cent surgical mortality rate.

7. Posterior parietal blow in skull E with 14.3 inch pounds of energy and sensitivity of lacquer at 0.00100 inch. Note the extensive deformations toward the phenoidofrontal junction

dline caused deformation patterns to appear on both sides. There is some variation in all to skull as concerns magnitude, but the direction of the paths of strain are the same (Figs. 3 and 4).

A frontal blow with 14.3 inch pounds of energy in the lateral frontal region caused strain patterns to appear in the parietal region and the frontosphenoidotemporal region. The cracks extend down and posteriorly near the zygomatic arch where their direction is downward and forward. In Figures 5 and 6 are shown the strain patterns following a frontal blow with a sensitivity of the lacquer at 0.00105 in both instances. Note that in these there are cracks in the lacquer covering the nasal bone.

Fig. 8. Occipital blow at the midline with 14.3 inch pounds of energy in skull E. Note the patterns over the squamous portion of the occipital and parietal bones. Note also the pattern at the base of the skull about the foramen magnum.

Lateral posterior parietal blow with 14.3 inch pounds of energy. Extensive deformations occurred with such blows. The paths of strain were downward and toward the "temple" (Fig. 7).

Midoccipital blow with 14.3 inch pounds of energy. A blow on the squamous portion of the occipital bone near the lambdoid suture at the midline caused some local deformations and deformations about the base of the skull at the foramen magnum (Fig. 8). In Figures 8 and 9 are seen differences in the magnitude of these strains, but the direction of the paths are the same. This may be in part explained by differences in skull

Fig. 9 Occipital blow in skull B with 14.3 inch pounds of energy. Sensitivity of lacquer at 0.00100. Extensive deformations are noted about the blow and at the base of the skull. This variation from skull to skull as concerns magnitude is seen frequently, but it should be noted that the distribution and direction of the patterns are essentially the same.

thickness and contour as well as by a slight change in the location of the blow from skull to skull. In one skull, "contrecoup" deformation resultant cracks in the lacquer were in the region on the frontosphenoid.

*No cracks.
Capital letters identify skulls and numerals following the letters signify test number.
Note: Tests B-7 and F-7 (Table I) in locations other than above shown, hence not included in this table.

Results with varying energies. Energies varying from 8 to 24 inch pounds were used in the midfrontal, midoccipital, and lateral posterior parietal regions of the skull. In order to obtain more reliable information varying energies were used in different locations on the same skull. These procedures were carried out on three specimens, and comparison of results lead to similar conclusions. Whereas in the occipital region an absorbed energy of 8 inch pounds causes threshold deformations, in the midfrontal region 14 to 18 inch pounds of energy is necessary to obtain beginning cracks in the lacquer. Eight inch pounds caused no deformations of sufficient magnitude to crack the lacquer in lateral posterior parietal blows, but threshold deformations were obtained with the use of 10 inch pounds. The illustrations for this portion of the work are photographs of the same skull struck with blows of varying energy (skull C, Table I).

Midfrontal blow with varying energies. In all skulls energies of 10 and 12 inch pounds caused no cracks in the lacquer. With 14.3 inch pounds the

Fig. 10. A midfrontal blow in skull C with 20 inch pounds of energy (left upper and lower); with 24 inch pounds of energy (right upper and lower). Note the increasing intensity of deformation patterns with increase in the injuring energy. Sensitivity of lacquer 0.00105 in both experiments.

results are shown in Figure 2. In Figure 10 are shown photographs of deformation patterns following the use of 20 and 24 inch pounds of energy. In Figure 11 are seen the lateral views of these skulls. With 20 inch pounds of energy, only faint and minor deformations are noted. With 24 inch pounds, the cracks are more evident, heavier, and more numerous and comparable to those obtained in the midoccipital blow with 14.3 inch pounds of energy.

Midoccipital blow with varying energies. Patterns were obtained with as little as 8 inch pounds of energy (the sensitivity of the lacquer at 0.00095). With 10 inch pounds of energy the deformations

are more extensive. With 14.3 inch pounds of energy the deformations at the base are more numerous and there are some cracks in the lacquer covering the parieto-occipital region. With 16 inch pounds of energy, the cracks in the lacquer extend to the base of the middle fossa, to the petrous bones and the zygomatic arches. The cracks are heavier, longer, and more numerous (Figs. 12 and 13). In Figure 14 are shown contrecoup deformations of sufficient magnitude to cause cracks in the lacquer at the frontosphenoidotemporal junction. They were first seen with 10 inch pounds of energy and are more extensive with blows of 14.3 and 16 inch pounds.

Fig. 11. Lateral view of skull C in experiments described in Figure 10. The upper two photographs show the results of a blow to the midfrontal region with 20 inch pounds of energy and the lower two photographs are the findings following a blow with 24 inch pounds of energy. Sensitivity of lacquer 0.00105 in both experiments.

With 8 inch pounds no contrecoup cracks were noted.

Lateral posterior parietal blow with varying energies. Lateral posterior parietal blows with 10 inch pounds of energy caused a few faint lines of deformation in the parietotemporal region. With 14.3 inch pounds the deformations were much more extensive as shown in Figure 15.

EVALUATION OF STUDY

The human skull is well suited for study with the "stresscoat" technique. After convincing experimental data (3) it was concluded that deformation patterns in the dry skull are the same as in the living. The influence of scalp and muscles on the strain path is negligible. It should be emphasized that this method shows only tensile strain. Compression strain cannot be visualized. It should also be noted that

the external surface of the skull has been studied thus far. Tensile strains of the internal surface are doubtless important following certain severe blows. Strain patterns may vary depending upon the location of the blow and small changes in location may produce altogether different paths of deformation. More work is needed to learn in greater detail the behavior of the skull to blows of varying location.

The strain paths depend upon the shape, contour, and thickness of the skull. Certain "chance" differences in skull thickness may produce profound differences in patterns. In our experiments, hammer and deceleration blows have been used. Actually, in automobile accidents and falls there be a combination of energies operating on the skull in succession or simultaneously in more than one direction. Depending upon the velocity of the formation patterns may be given a certain

behavior

Fig. 12. Midoccipital blow with graduated energies on skull C. To the left, results with 8 inch pounds of energy and sensitivity of lacquer at 0.00105; to the right, results of a blow with 10 inch pounds of energy with sensitivity of lacquer at 0.00105.

directional quality. High velocity energies may cause localized deformation with comminution, depression, or perforation of bone. At the present time, we have no information concerning the behavior of a skull with energies of high velocity. In the present study velocities at the instant of impact varied between 5.4 and 9.9 feet per second.

In general, the paths of strain brought out by these studies parallel fracture lines seen clinically in the human. The deformation patterns are more common in the weaker than in the buttressed zones of the skull (4). Thus, very few cracks are seen in the lacquer extending longitudinally along

the median plane of the frontal and occipital bones. Relatively few deformation patterns are seen along the zygomaticofrontal and the petrosoparietal buttresses. Clinical data corroborate these findings. Fractures resulting from general deformations of the skull in general follow the strain paths seen in these experiments. With blows in the posterior parietal region, a fracture line extending down and forward toward the temple is commonly seen. Fracture lines in the occipital bone in general follow the strain paths seen in these tests. The three types of fracture seen include linear fractures extending into the

Fig. 13. To the left, an occipital blow with 14.3 inch pounds of energy and sensitivity of lacquer at 0.00105; to the right, an occipital blow with 16 inch pounds of energy and sensitivity of lacquer at 0.00095 inch per inch (skull C).

foramen magnum, linear fractures extending lateral to the foramen, and fractures which extend down toward one or the other of the large openings at the base of the skull such as the jugular foramen or the hypoglossal foramen. These may then extend forward toward the petrous bone. Fracture lines in frontal blows are usually seen extending toward the roof of the orbit in a paramedian position, much in the same direction as in the strain paths with midfrontal blows. It is obvious that with high velocity energies there may be localized deformation with comminution, depression or perforation. It has also been men-

tioned previously that depending upon the size, shape, and velocity of the injuring object, a certain direction may be given the strain paths.

Certain threshold values may be deduced from a study of Table II. Whereas in the occipital region 8 inch pounds of energy are sufficient to cause deformation patterns in the lacquer of the sensitivity used, in the midfrontal region 14 to 18 inch pounds of energy are needed for deformations of similar magnitude. In the parietotemporal region, threshold values are obtained with 10 inch pounds. It is therefore apparent that relatively minor blows may result in deformation

Fig. 14. Lateral view of skull C with midoccipital blow of 10 inch pounds of energy, 14.3 inch pounds of energy and 16 inch pounds of energy. Note that with 10 inch pounds (upper row) deformations are only slight; with 14.3 inch pounds they are more extensive (middle row), and they are most widespread with 16 inch pounds of energy (lower row). The deformation patterns are found at the frontosphenoidotemporal junction on one or both sides (contrecoup deformations).

Fig. 15. Lateral posterior parietal blow in skull C with 10 inch pounds of energy (upper row), and 14.3 inch pounds of energy (lower row). The sensitivity of the lacquer 0.00095 and 0.00100, respectively.

of the skull with failure in certain regions. The case with which deformations are produced in the region of the foramen magnum and parieto-temporal regions may explain how in certain injuries linear fractures may obtain in these locations without loss of consciousness. A small amount of energy may be dissipated in causing deformation and failure of the skull. However, it may not be of sufficient magnitude also to result in adequate pressure waves in the cranial cavity to cause posttraumatic unconsciousness. A severe blow in the occipital region is associated with extensive deformation at the base of the skull thus helping to cause intracranial pressure waves to add to the serious intracranial injury. Whereas a weak blow may cause a symptomless fracture line, a severe blow may result in a serious state. It is clinically known that patients with

fracture of the base may be seriously ill and yet there are instances in which the symptomatology is very slight.

In one skull (C), occipital blows were consistently associated with deformation patterns at the frontosphenoidotemporal junction on one or both sides. From their position, they may well be called contrecoup deformations. Contrecoup fractures may thus be possible. Clinically, the association in some cases of "black eyes" with a fall resulting in an occipital blow may be explained by contrecoup deformations in the region of the origin of the temporalis muscles with postpalpebral bleeding.

SUMMARY

1. The amount of absorbed energy necessary to cause threshold deformations is different in vari-

ous parts of the skull. In the midfrontal region blows of 14 to 18 inch pounds of energy cause deformations of a magnitude similar to those obtained with 8 inch pounds in midoccipital blows.

2. A small amount of energy may be dissipated in deformation and failure (fracture) of the skull. However, it may not be of sufficient magnitude also to result in adequate pressure waves in the cranial cavity to cause posttraumatic unconsciousness. This may explain how in certain locations of the skull linear fracture may obtain without unconsciousness.

3. Contrecoup deformations of the fronto-sphenoidotemporal junction following midoccipital blows were obtained in one out of six skulls.

This argues in favor of contrecoup fractures in certain cases.

4. The distribution and direction of deformation patterns generally parallel fracture lines in clinical cases. However, the shape and velocity of the injuring object may influence and give strain paths a directional quality.

SPONTANEOUS RUPTURE OF THE ESOPHAGUS

E. L. ELIASON, M.D., F.A.C.S., and R. F. WELTY, M.D., Philadelphia, Pennsylvania

SPONTANEOUS rupture of a presumably normal esophagus has been reported only infrequently. The occurrence, therefore, of 3 cases in a period of 1 year in the experience of the senior author has prompted us to report these cases and review the literature.

The earliest case recorded is one by the Dutch physician Boerhaave, in 1724 (12). His brilliant description over 200 years ago of the onset and course of the disease and of the findings at autopsy leave relatively little to be added today. A few lines with regard to this report therefore are of interest:

Quoted from van Swieten: "We have a surprising observation given us by the celebrated Boerhaave which is, perhaps the only one published, namely, the illustrious Baron Wassenaer, Lord High Admiral to the Republick, after intense straining in vomiting broke asunder the tube of the esophagus, near the diaphragm, so that after the most excruciating pains the aliments which he swallowed passed, together with the air, into the cavity of the thorax, and he expired in twenty four hours."

Quoted from Liebetaud: "From him (Boerhaave) it appears that the Admiral, who was more than fifty years old, suffered an annoyance at the pit of the stomach three days after feasting sumptuously. During the efforts to obtain relief by vomiting, the sudden pain, 'as from some rupture or tearing' occurred. During the progress of the affection he was constantly tortured with extreme pains. In the meantime increased suffering threatened syncope; there was neither fever, cough nor difficult breathing. The vehemence of the pains prevented any motion of the body and there was scarcely any remission from their great severity. They seemed to be seated primarily within the chest near the diaphragm, thence extended to the back and throughout the entire chest. Finally the strength gave way and he died suffocated, the horrid symptoms continuing. Nothing noteworthy was found in the abdomen; a large amount of gas escaped from the first incision into the pleural cavity. The lungs and heart were unaffected. A marked and unusual smell came from the chest, as if proceeding from some putrid fluid in which the posterior parts of both lungs were bathed; this fluid, amounting to six pounds, did not differ in the least from the con-

tents of the stomach. The body having been thoroughly cleansed, there was found a transverse rupture through the esophagus near the diaphragm."

The first review of this subject in the American literature was by Reginald Fitz of Boston in 1877 (12). He recorded a case of his own and described the disease at some length. The next comprehensive review appeared in 1914 (55). At that time Walker was able to find only 22 cases recorded in which rupture took place spontaneously in an esophagus otherwise normal. His case is the first of the 4 reported in the literature which have been diagnosed before death (1, 16, 50, 55). Since Walker's review several articles on this subject have appeared (1, 8, 16, 19, 32, 41, 50). Most have been solitary case reports. However, Gott in 1933 in a 10 year review of all admissions to the Louisville City Hospital was able to find 4 cases. Ridgway and Duncan in their review of 1937, believe that 3 of these cases are not representative of true spontaneous rupture. The latest review by Klein and Grossman in 1943 included only 40 cases gathered from the literature. We have been able to find only 1 case report since then (8). In contrast to rupture, perforation of the esophagus is not uncommon. It may follow the ingestion of a foreign body (3, 5, 18, 28, 30), instrumentation (21, 23, 25, 26, 53), external trauma (31) or erosion of a carcinoma, or result from a stricture (54) or syphilis (15). This is not the sort of injury under consideration, however.

Spontaneous rupture of the esophagus occurs at the lower end—usually within an inch or two of the cardia. At times the rupture extends down into the cardiac portion of the stomach. The posterior or posterolateral wall usually on the left side is the site most commonly involved. The rupture is usually a solitary one and in only 2 of Walker's 22 cases failed to be a longitudinal slit-like opening. The fissure may be one to several centimeters in length. Though in some cases there is evidence of pre-existing ulceration usually the mucosa and muscular coats are quite normal except for the immediate site of rupture.

Congenital weakness of the area seems unlikely as an explanation for the rupture. Twenty-five of the 35 cases reported by Ridgway and Duncan occurred during the third, fourth, and fifth decades of life. Menne and Moore could find only 3

additional procedure of exploration of the common duct was limited to those in which indications were definite, and these totaled 47, or 8.9 per cent. The policy has been adhered to that the welfare of the patient is continually to be kept in mind and that the operative procedure employed is to be that which promises the greatest possible benefit and least hazard. The operation is not decided upon entirely before the procedure is undertaken. For instance, if during operation cholecystostomy seems to be the procedure of choice, cholecystectomy is abandoned.

Cholecystostomy was performed in 67 instances and was followed by 5 deaths. This procedure is clearly indicated when the patient is too ill to withstand cholecystectomy or when cholecystectomy presents too great difficulties. For the extremely debilitated patient or for the very ill, we doubt if there are any contraindications for cholecystostomy. It may be done under local anesthesia, disturbing the patient very little; and it may be a life-saving operation. The decompression of the biliary tract averts catastrophe by preventing progressive liver damage if complete biliary obstruction is present.

In determining the type of operation to be done, the gross appearance of the presenting pathological changes is of importance. In the first place, if there is gangrene and perforation with accompanying generalized peritonitis, simple drainage of the abdomen together with cholecystostomy is indicated. If there is gangrene and perforation which has resulted in localized peritonitis or abscess in the region of the extrahepatic portion of the gall bladder, then one may choose between cholecystectomy and cholecystostomy. However, in the presence of extensive adhesions of the omentum to the gall bladder and into the

biliary fossa, it is indeed questionable whether these should be disturbed and a cholecystectomy done. If the patient is unusually ill and if postoperative complications appear in the offing, then certainly cholecystectomy should not be attempted. Perforation of the gall bladder with a small abscess or perforation into the adjacent liver tissue is no contraindication to cholecystectomy. The patients with simple acute cholecystitis are in general best treated by cholecystectomy.

Common duct exploration in acute cholecystitis has been limited in our clinic to those patients with unequivocal indications for common duct obstruction. If these exist, common duct exploration should be undertaken even though it adds additional risk to the procedure. The incidence of postoperative complications is in this series apparently increased. At the same time it may be said that these patients are usually in the group that is more seriously ill. For the extremely ill, jaundiced patients, decompression (that is, cholecystostomy) may be utilized as a compromise procedure, having in mind, of course, following the subsidence of jaundice, the exploration of the common duct with the patient in a greatly improved condition.

The presence of jaundice requires the determination of blood prothrombin and the evaluation of any bleeding tendency, and, in the presence of acute disease, time may not be afforded for this. For such patients the use of whole blood transfusions and parenteral administration of vitamin K may prevent serious postoperative hemorrhage.

The common duct was explored in 47 of the patients in this series, an incidence of 8.9 per cent. Stones were recovered in 29 of these, or 61.7 per cent. It is probable that the opening

cases in childhood—a time when congenital abnormalities are likely to become manifest and when vomiting is especially prone to occur. Also the reported cases usually do not present thinning of the muscular coats.

Ulcerative esophagitis and peptic ulcer of the esophagus are entities which are now recognized and perforation and hemorrhage can occur in these ulcers (4, 13, 27, 38). It is questionable whether such cases should be included in a consideration of spontaneous rupture of the esophagus. The possibility of an acute linear peptic ulceration in the remaining cases still is present. Moreover the factor of peptic digestion of a traumatic fissure is even more difficult to rule out. Two cases have been reported of rupture of the esophagus after extensive burns (49, 51). In 1 Curling's ulcers were present also in stomach and duodenum (51).

There seems little question that the most important factor in spontaneous rupture of the esophagus is that of sudden increase in pressure. Cases have been recorded following crushing injuries of the abdomen, (1, 41) during convulsive seizures (32), and during defecation (42). In 23 of the 35 cases reported by Ridgway and Duncan vomiting had preceded the rupture. Of the 25 in whom an accurate history could be obtained, 18 were alcoholics. Though the alcohol in itself may have a deleterious effect on the esophagus, it seems likely that the nausea, retching, and vomiting associated with excessive drinking are the more important factors in rupture.

In 1884 (8) McKenzie demonstrated experimentally that the lower end of the esophagus is the weakest portion. Weiss and Mallory (37, 56) were able experimentally to reproduce linear fissures of the lower end of the esophagus and cardia by increased pressure.

Weiss postulated the following (20): Vomiting is a complicated and highly co-ordinated mechanism. The pylorus closes and the cardia and esophagus dilate. A wave of counter peristalsis is set up, and the esophagus relaxes. A sudden convulsive rise in intra-abdominal and intragastric pressure empties the stomach. If vomiting is repeated the vomiting center becomes fatigued. Co-ordination is lost and the esophagus and diaphragm fail to relax in the face of the sudden increase in pressure, resulting in rupture. The fact that at least 2 cases (12, 54) occurred during strenuous vomiting in attempts to dislodge a bolus of food in the esophagus would lend support to this theory. Rupture has been reported in association with neurogenic disturbances but this is certainly uncommon and an unimportant and irrelevant factor in this presentation (9, 39).

In only 5 of the 35 cases reported by Ridgway and Duncan were the patients females. The significance of this is not certain unless the picture of alcoholism is considered predominant in the male.

Rupture of the esophagus usually takes place during an episode of vomiting, often precipitated by a bout of drinking or a heavy meal. The patient experiences sudden severe pain high in the upper abdomen or epigastrium or beneath the sternum. Frequently the pain radiates to the back or to the interscapular region—the left side being more often the site of reference than the right. With the onset of the pain, some have felt a sensation of something tearing or giving way in the chest. If vomiting is repeated the vomitus is likely to be bloody. Though the pain is usually severe and persistent and often is not relieved significantly by morphine, in some cases the pain has not been severe but has been more in the nature of a pressure or discomfort in the region of the rupture. Food particles are often found in the posterior mediastinum. Rupture into the pleural cavity (usually the left) is not uncommon. If this be true gastric contents may be found here also. Even though the pleural cavity is not actually invaded, pleural effusion is often present because of the adjacent mediastinal irritation. Though hemorrhage may be rather profuse after rupture the real threat to the patient is that of a fulminating mediastinitis and death. There has been no case reported so far in the literature in which recovery has taken place, though in an editorial footnote in the 1944 *Yearbook of Surgery*, Graham mentions 2 cases which resulted in empyema and recovery following drainage of the empyema. This same course has been reported following perforation of the esophagus.

On examination the patient is found to be obviously critically ill. Shock is profound. Thirst is extreme and the patient may be able to take fluids by mouth with little difficulty or discomfort, though some discomfort may be felt locally at the site of rupture as the material swallowed passes over it. The blood pressure is low, the body temperature may be depressed and the pulse is rapid. The skin is cold and clammy; there is a pallor which quickly gives way to marked cyanosis. Dyspnea is often present and the respiratory rate is increased.

Initially findings on examination of the chest may be normal, and the upper abdomen is somewhat tender and guarded. However, as time passes the abdominal signs tend to diminish and the chest signs become more prominent with the development of rales and dullness at the lung bases. Some have been able to detect an abnormal

sound of fluid and air in auscultation of the chest during the swallowing of water. In about half the cases subcutaneous emphysema eventually develops. It is manifested first in the suprascapular fossae and the suprasternal notch but later extends to involve the entire neck, face, trunk, and even the extremities. Wangenstein once said: "In the drowsy small hours of the night, I have once made the diagnosis of spontaneous perforation of the lower esophagus over the telephone in conversation with the surgical resident on the basis of subcutaneous emphysema in a patient who had upper abdominal pain, no dyspnea, or cough." (45). If rupture extends into the pleural cavity physical signs of hydropneumothorax develop and gastric contents may be aspirated from the chest. Three cases diagnosed before death were discovered in this way (1, 16, 50). X-ray examination usually shows mediastinal emphysema within a few minutes of the time of rupture, long before the air becomes evident in the subcutaneous tissues of the neck. A fluid level in the mediastinum may also be demonstrated by x-ray examination.

The differential diagnosis includes coronary occlusion, dissecting aneurysm of the aorta, pulmonary embolism, spontaneous pneumothorax, ruptured peptic ulcer, acute pancreatitis, and mesenteric occlusion. The abdominal pain is so prominent a feature that many have been subjected to exploratory laparotomy (1, 24, 52, 55).

CASE REPORTS

CASE 1. L. B. H. This 55 year old white man, was admitted September 18, 1944. He was a known alcoholic for many years and had recently been on a prolonged spree. The day of onset of his illness he did not feel well but had no particular complaints until 6:00 p.m. when he suddenly vomited before dinner. Some blood was seen in the vomitus. There was some upper abdominal pain and substernal distress but no rigidity of the abdomen and little tenderness. His pain increased and the upper abdomen became rigid. In addition a tightness of the lower chest was noted. The diagnosis of ruptured gastric or duodenal ulcer or acute pancreatitis was considered so he was explored 6 hours after the onset of his trouble. Nothing was found. He continued to vomit bloody material and gastric suction drainage was instituted. In spite of supportive treatment he failed to do well and showed marked circulatory collapse. The senior author was called in consultation the following morning. At this time subcutaneous emphysema was found on both sides of the neck. A chest film showed air in the mediastinum. An electrocardiographic tracing was normal. The serum amylase was 75. A diagnosis of rupture of the esophagus was made. The patient was *in extremis* at the time, however, and nothing could be done. He died at 6:00 p.m. that night, 24 hours after the onset of his illness.

At autopsy there was found a longitudinal rent 3 centimeters in length at the lower end of the esophagus. The surrounding mediastinal tissues up to the bifurcation of the trachea were inflamed, discolored, and necrotic. The right pleural cavity contained 450 cubic centimeters of clear

amber fluid and the left 600 cubic centimeters with much admixture of blood on this side. The mediastinal borders of both lungs adjacent to the area of rupture showed fibrinous exudate. The stomach and duodenum were normal. However, blood was present in the intestinal tract.

CASE 2. No. 42030. This 76 year old white man was admitted to the Hospital of the University of Pennsylvania on October 16, 1944, on the service of Dr. Edward Rose and Dr. William H. Erb. In 1939 a resection of the sigmoid was carried out because of a nonspecific infectious granuloma. A fecal fistula had persisted following the resection. For a few days prior to the present admission he had suffered some nausea. At 10 a.m. on the day of admission he had a sudden onset of vomiting. A second bout of vomiting contained blood. In a few minutes excruciating pain in the left lower chest and back developed which could not be relieved by morphine. The chest was clear on admission. His white blood count was 16,000. A survey film of the abdomen showed only large bowel distention. A chest film was negative. The electrocardiographic tracing was equivocal. He went into profound circulatory collapse and died 19 hours after the onset of his illness.

The clinical diagnoses included: coronary occlusion, dissecting aneurysm, and mesenteric thrombosis. Rupture of the esophagus was also considered when the senior author was called in consultation since Case 1 had been seen by him only the month before.

At autopsy the right pleural cavity was free of fluid. The left side contained air under pressure and 1500 cubic centimeters of brownish red fluid with clots. There was rupture of the mediastinal pleura in the region of the esophageal hiatus, and the lung was collapsed. A longitudinal rupture of the esophagus was found, 3 centimeters in length at the esophagogastric junction with no evidence of pre-existing ulceration. Two benign prepyloric ulcers were found in the stomach.

CASE 3. E. Y. No. 65235. This 44 year old white woman was admitted on August 25, 1945, to the senior author's service at the Hospital of the University of Pennsylvania with a history of abdominal pain of 30 hours' duration, requiring morphine for relief. Though there had been some nausea and vomiting these were not prominent features in the history. On examination she was found to have a tender mass in the left lower quadrant, also felt on pelvic examination. A diagnosis of strangulation was made and exploration was carried out the day of admission. A gangrenous loop of ileum was found. Resection and primary anastomosis were performed. She did very well for 24 hours after operation. Her abdomen was soft and flat and peristalsis was present. Suddenly she developed a heavy substernal pressure with palpitation and generalized weakness and a sensation of smothering. She was pale and had a marked tachycardia. A medical consultation was obtained and an electrocardiographic tracing was done. Coronary occlusion could not be ruled out, but the consultant felt that pulmonary embolism was a more likely diagnosis. She was given morphine, oxygen, and plasma and seemed to rally for a time. Ten hours later, however, she again developed substernal distress, palpitation, and weakness. She went into increasingly profound peripheral circulatory collapse with intense cyanosis and cold clammy extremities. The pulse became imperceptible and the blood pressure unobtainable. A second electrocardiographic tracing was made and no changes could be found in it which were not consistent with profound circulatory failure. A Levine tube had been placed in the stomach following operation. The tube was removed at this time (35 hours after operation) because of respiratory distress. Repeated vomiting of coffee ground material followed removal of the tube, but it was not replaced because of fear of trauma to the bleeding site.

She failed to respond to treatment for shock and died, 30 hours after her first attack of substernal distress and 54 hours after operation.

At autopsy there was found a rupture of the anterior wall of the esophagus at the distal end. The rent was about 1.5 centimeters in diameter. The surrounding wall showed thinning of the muscularis. The adjacent mediastinal tissues were deeply stained with partially digested blood. The pleural cavities contained small amounts of straw colored fluid.

The possible rôle which the Levine tube may have played in this case is uncertain. Constant gastric suction drainage is now often used for periods of much longer than 24 hours with no difficulty at all. Of passing interest was the discovery at autopsy of an adenoma the size of a walnut in the cortex of the right adrenal (unsuspected).

Spontaneous rupture of the esophagus is no doubt much more common than appreciated. Many of the deaths in the past must have been erroneously attributed to the factors listed in the differential diagnosis. Postmortem examination is necessary to rule out the disease and has been the sole method of diagnosis in most of the cases reported. An autopsy, unless carefully conducted, may overlook the lesion. If the esophagus is divided just above the cardia and not removed *en bloc* with the stomach, the pathologic picture may be missed or destroyed.

Ninety per cent of perforations of the esophagus occur in the cervical region (22). For a long time the anatomy of the neck (7, 11, 33) and the methods of spread of infection in it (43, 45, 47) have been well understood. Many cases of perforation in this area have recovered following prompt anterior cervical mediastinotomy, even without the aid of chemotherapy (2, 6, 22, 29, 44, 46). This approach is of value for perforation or infection only above the level of the fourth or fifth dorsal vertebra—a level well above the area of the mediastinum involved in spontaneous rupture of the esophagus.

Posterior mediastinotomy was first described on the cadaver by Nassilow in 1888 (14). In 1898 Cavazzoni drained an abscess in the posterior mediastinum by the dorsal approach with recovery of the patient (14). The approach is now well understood and many patients have since been drained in this way with recovery (34, 35, 36). These have all been cases of a perforation recognized immediately or of a localized abscess. With the agents now available the question rises as to whether chemotherapy alone can replace operation in rupture or perforation of the esophagus as in the case reported by Heatly. It seems likely that extensive rupture with gross contamination of the mediastinum will still require drainage.

The mortality reported so far in spontaneous rupture of the esophagus is 100 per cent excluding the 2 cases mentioned by Graham. Most patients succumb within 24 hours though 1 patient survived 17 days (16). With improved techniques in anesthesia, freer use of blood and plasma for intravenous infusion, and effective chemotherapeutic agents, the limiting factor in the treatment of this condition is that of diagnosis. It does not seem at all unlikely that soon recoveries from this condition will be reported. Prompt resort to the use of roentgenography and esophagoscopy in questionable cases should enable one to establish the diagnosis early. Just as in perforation of the cervical esophagus, prompt operation leads to a low mortality (45) so prompt recognition of spontaneous rupture of the esophagus will be necessary if recoveries are to be obtained.

the ducts and acini of breasts belong most likely in the same category.

It is noteworthy in reviewing the voluminous literature on the relationship of chronic cystic mastitis to cancer that opinions vary from nil to 20 per cent, which again brings to one's realization a bewildering conflict of opinions. Bloodgood, who had been a contemporary advocate of the casual relationship of chronic mastitis to cancer of the breast, had a change of mind after a more profound study of the subject. He was the first really to challenge, in 2 masterful papers, the concept that had prevailed for many years. In the first in 1921, he reported 128 cases in 3 of which cancer developed; in the second in 1929, he reported 500 cases in only 5 of which cancer developed, an incidence even less than occurs in the absence of cystic disease. His studies are of particular value since they combined and correlated the microscopic picture with the clinical course of the disease in some instances for 29 years.

Bloodgood submitted sections of every type of chronic cystic mastitis to more than 40 consulting pathologists. In the majority of cases there was disagreement. The percentage of those favoring benignancy varied from 20 to 90; furthermore, in tissues and sections that were sent to him for diagnosis he had never received one which proved to be a fully developed cancer that had not been diagnosed cancer, whereas he had received many with the diagnosis of cancer which in his opinion belonged to some form of chronic cystic mastitis, further illustrating the difficulties of the histologic interpretation of the nature of growth—or overgrowth. He concluded by saying that in breast lesions when good pathologists disagree as to malignancy, the patient lives. When there is agreement there is always a large percentage of deaths from cancer.

Reclus, an outstanding student of the subject, in 1883, 38 years before Bloodgood's challenge, also had a change of mind. While he originally believed in the benignancy of cystic disease, he had been influenced by the pathologist to question his stand only to revert to his original opinion after further study of his cases upon learning that those that had been treated conservatively remained well.

In 1934 Campbell summarized the literature and contributed a series of 290 case studies of cystic disease with clinical follow-ups from which he was compelled to conclude that cystic disease is not a precancerous lesion; that malignant changes are no more likely to follow this disease than to occur in breasts that are entirely free from this condition. He includes in this study the

adenocystic (Schimmelbusch's disease) variety. Two patients of the 290 cases reported developed breast cancer—0.7 per cent. He contends that the clinical test of time is the true answer to the controversy.

Lewis and Geschickter in 1938 reported 515 cases of cystic disease. Two hundred fifty of this number were followed for more than 5 years. One of this group of 250 died of breast cancer, an incident of 0.4 per cent. From this study it is their conviction that cystic disease is not a precancerous lesion.

Warren in 1940 presented a comprehensive study in which he concluded that 4.5 times as many cases of chronic cystic mastitis subsequently developed cancer of the breast, age for age, as would be expected for the female population as a whole. His studies include all forms of mastitis. He does agree, however, that the large, clinically palpable cysts with atrophy of their lining epithelium are less likely to be followed by cancer than are those with active, often papillary, epithelium and that aspiration of the contents may be a justifiable therapeutic procedure. However, he believes excision to be preferable since it is difficult to determine the exact nature of cell hyperplasia if present.

Thus it is evident that whether hyperplastic cystic disease (large simple cysts, papillary cysts, papillary cystadenomas and duct adenomas) is endowed with malignant qualities or not is a question still not settled. It is however, fair to state that all students of the subject agree that the larger (clinical) cysts are relatively harmless. There are those who believe that they are entirely harmless. Yet in recent times no one seems to have the conviction or courage to treat these large simple cysts by puncture.

For reasons already stated, to remove a large cyst, in which there is little or no hyperplasia of the cells of the walls, while leaving innumerable smaller cysts, also acini and ducts with definite hyperplasia of cells, is inconsistent and unsound reasoning. And to repeat also, that which cannot be felt or seen (still) causes no concern.

That these simple cysts are harmless, in so far as being forerunners of malignancy is concerned, became my conviction 14 years ago. Since that time I have managed simple cysts by puncture as a diagnostic and therapeutic office procedure.

In making the clinical examination the experienced observer can in a goodly number of cases be correct in his conjecture as to the nature of the lump he is dealing with but this conjecture must be verified. A cyst of clinical size if superficially located transmits, as a rule, to the exam-

ining hand, the feel of just what it is—a cyst that is tense but not hard as is a fibroadenoma. While movable, it does not “shuck” around like a fibroadenoma or a lipoma (rare). The deeper lying cyst often imbedded in dense and thickened connective tissue stroma cannot be differentiated by the feel from malignant growths. In either case there is no skin attachment.

The following is the office procedure for diagnosis. In the absence of clinical signs of malignancy the overlying skin is injected with local anesthetic by means of a fine needle; a larger needle is then introduced into the lump. If it is a cyst the plunger of the syringe will be pushed up by the fluid under tension. Pressure with the fingers over the lump area helps to remove the last drop of fluid, so to speak. Few cysts so managed refill. It has been conjectured that it is because of complete emptying that so few refill. From my experience I have learned to form an opinion on the nature of a lump, that is not a cyst. A fibroadenoma is tough like rubber; a thickened wall of a deep seated cyst is likewise rubbery; a medullary carcinoma is soft, as is a lipoma; a scirrhous carcinoma transmits a gritty feel. While this interpretation of “feel” has no special practical value it is a refinement in clinical diagnosis and gives some satisfaction when committing oneself to a definite preoperative diagnosis.

This report of 57 case studies is limited to clinically palpable, large simple cysts exclusive of other forms of cystic mastitis. While the number of cases is not large, its importance lies in the period of observation; namely, 14 years. All have been followed and checked to the present time.

Age incidence. The peak of incidence was in the latter half of the fourth decade. The youngest subject was 27 years of age; the oldest 62 years. In the 26 to 30 year age group there was 1 case; in the 31 to 35 year group, 5 cases; in the 36 to 40 year group, 13 cases; in the 41 to 45 year group, 13 cases; in the 46 to 50 year group, 2 cases; in the 56 to 60 year group, no cases; in the 61 to 65 year group, 1 case.

Child bearing. Twenty-six of the 57 patients had borne children; 30 were childless; in 1 patient, not recorded.

Number of cysts. The 57 patients had a total of 123 discernible cysts; 15 patients had cysts in both breasts. Thirty-three had 1 cyst, 12 had 2 cysts, 2 had 3 cysts, 4 had 4 cysts, 4 had 6 cysts, 1 had 9 cysts, 1 had 11 cysts.

Incidence in right or left breast. The left breast harbored slightly over twice as many as the right; left breast, 29 cases; right breast, 13 cases. In 1

of these patients an early carcinoma was present in the opposite breast. Both breasts were involved in 15 patients.

Location. The upper hemisphere, especially the upper outer quadrant, is more often affected than the lower in the ratio of 3 to 1.

Size. The size of the lumps varied from a hazelnut to a tennis ball; the average from a hazelnut to a walnut. The amount of fluid varied from $\frac{1}{2}$ to 45 cubic centimeters, the average from $\frac{1}{2}$ to 10 cubic centimeters.

Character of contents. Cloudy, grayish with a greenish cast is the usual appearance of the contents; less frequently it has a brownish cast. In 2 cases, the cysts were blood containing; one was excised. The other patient, one of the earlier cases, procrastinated but no trouble followed.

Dry puncture. In 2 cases, deep seated lumps proved on excision to be cysts embedded in dense heavy connective tissue stroma. The needle had gone past the cysts which were small—the size of a hazelnut.

Mastectomy. In 2 cases, multiple large cysts in both breasts embedded in heavy dense stroma, kept on refilling and were painful; these were finally treated by mastectomy. In only 3 other cases, as far as could be ascertained, was there refilling.

Simple cyst and early malignancy. One patient had a cyst in one breast; a small lump in the other that gave a dry tap proved upon excision to be an early carcinoma and was treated accordingly. There was no histologic evidence that the malignant lesion had its origin in mastitis of any form. This was the only malignant growth encountered in the series of 57 cases.

The 57 patients were spared 83 surgical operations in all, since in several cases cysts appeared subsequently.

DISCUSSION

The report of this series of cases may not be sufficiently convincing to settle an old argument. However, study of clinical cases followed through for as long as 14 years, average $7\frac{1}{2}$ years, is strong evidence. The behavior of growth is, in the last analysis, the answer to its nature. It should be more convincing than the evidence of microscopic interpretation of growth which, admittedly, is not infrequently difficult and erroneous.

The nature of every lump in the breast must be determined. (One case of a cyst in one breast; an early carcinoma in the other).

It is said that simple cyst lumps cannot with real certainty be differentiated from cancer by palpation. The answer to that is needle puncture—most simple, an office procedure. It gives identi-

cal information and the same protection to the patient that is obtained by excision. It is equivalent to the discovery by the surgeon that the lump excised is a cyst, whereupon also the surgeon carries the operative procedure no further. In the event of multiple cysts or others to appear, it becomes then a piecemeal, unsatisfying job of surgery. Such instances come to one's attention not infrequently. All in all, in that case, it means the hard and costly way for the patient.

In the 57 cases comprising this study, there was one instance of early malignancy in one breast; a simple cyst in the opposite one, in a patient 50 years of age—an incidence of 1.7 per cent; normal incidence said to be approximately 2 per cent.

The fact that whereas chronic cystic mastitis is one of the commonest lesions found in the female breast, yet cancer of the breast occurs in relatively only a small percentage (approximately 2 per cent) of individuals, is in itself strong evidence to absolve chronic cystic mastitis from being a forerunner of breast carcinoma.

The more recent exponents of the benignancy of simple cysts of the breasts notably Bloodgood,

Campbell, Lewis and Geschickter still advocate excision for the most part. The author's experience is in agreement as to the benignancy of simple cysts but he differs only in the management of them, in that he has practiced simple puncture consistently for the past 14 years as a diagnostic and therapeutic office procedure. The patient is thereby afforded protection equal to that of excision. At the same time it has spared her the ordeal of an operation—or even operations, with all it entails—not excluding hospital cost and surgeon's fees.

NOTE.—Any one not trained, skilled, and experienced to do radical breast surgery should do neither a simple puncture nor a biopsy.

SURGICAL ASPECTS OF TRENCH FOOT

ROBERT R. BATES, M.D., F.A.C.S., Major, M.C., Joliet, Illinois

ON February 7, 1945, this former Army Service Forces Convalescent Hospital was designated a general hospital, largely for the treatment of trench foot and frostbite injuries. In addition, a portion of the camp facility has been rebuilt to function separately as a convalescent hospital, and the two institutions, grouped together, comprise a hospital center for the study, treatment, rehabilitation, and disposition of trench foot cases. During the 4 months between February 7, 1945, and June 7, 1945, 4,892 soldiers with frostbite and trench foot were admitted to this hospital center. Many were litter cases on arrival; more, however, were ambulant. Originally, all were assigned to the medical service. There, the great majority became not only ambulant, but reached a maximum degree of hospital benefit; 264 had varying degrees of persistent gangrene, and it was a policy of this medical department to transfer these cases to surgery after they had attained maximum improvement on the medical regimen. The time involved in gaining this improvement varied from 4 weeks to 2 months.

At this point, the current concept of trench foot might be briefly mentioned because it is upon it that the rationale of treatment is based. Main factors concerned in the development of this injury apparently are the following: (a) Exposure to cold but not necessarily freezing weather for (b) varying lengths of time from a few hours to, usually, several days, and occasionally much longer periods, during which (c) the feet are wet or at least damp, and, in addition, are (d) constricted by foot gear that is not too tight for ordinary wear but is too tight for feet beginning to swell, and finally, but not the least factor in importance, (e) prolonged relative immobilization of the whole body, particularly the dependent legs and feet. This prolonged exposure, in which tight shoes and wet socks enclose cold and immobile feet, brings about trench foot. Perhaps, in some

cases, all these factors need not be present to bring it on, but if all are present, its development is quite likely. Relative malnutrition and fatigue may occasionally be additional factors.

Early, it is known, there occurs reflex capillary and arteriolar vasoconstriction. Anoxemia of all tissues of the toes and foot follows for this reason, and also because of lessened oxyhemoglobin dissociation which occurs at low temperatures. Anoxemia leads to damage to all affected tissues. At this stage, the feet are insensitive but hours later, on removing the feet from the faulty environment, a contrasting reaction occurs. Feet and toes become red and hot to palpation, and burning hot subjectively. They swell and the toes become dusky. Hemorrhagic blebs may appear on both soles and dorsum of feet and toes. At this early stage it is believed the capillaries are dilated, their endothelium damaged and the capillary stream slowed. Increased capillary permeability leads to increased exudation into interstitial and intercellular spaces of the foot. So much fluid escapes that the edema may appear in the epidermis as blebs. The anoxemia, already aggravated by edema, is further increased by thrombosis of many small arterioles, consequent upon their damaged endothelium and vascular stasis. If during this stage the foot be heated or exercised as a therapeutic measure, all these unfavorable factors become aggravated. Local nerve tissue also suffers from anoxemia. Due either to irritation or destruction of peripheral nerve elements, vasomotor changes follow, also sensory and, presumably, trophic changes as well. All other structures also suffer. As the edema subsides, an inflammatory type of repair occurs in the viable areas above the demarcation line. The end-result is fibrosis, not only of the subcutaneous tissue where fat has been lost, but of intrinsic foot musculature as well. Tendon sheaths become involved in adhesions. Joint capsules acquire adhesions and frequently there results a chronic noninfectious arthritis and synovitis. Periosteum may thicken and bone cortex becomes decalcified. Marrow may become replaced by fibrous tissue. Toe nails exhibit evidence of an arrest in growth. A transverse raised ridge may later be seen growing out of the nail bed and for many months the nail is thickened and deformed. Typically a mixed type infection exists at the demarcation

From the Surgical Service of the U.S. Army General Hospital, Camp Carson, Colorado.

The following additional officers participated in the surgical care of these cases and contributed to the opinions and evolution of surgical principles outlined in this paper: V. L. Hart, Lieutenant Colonel, M.C.; Seventh Service Command orthopedic consultant; Harry W. Woodward, Lieutenant Colonel, M.C.; Harold L. Gordon, Major, M.C.; Jesse F. Harrold, Major, M.C.; Norbert J. Kulzer, Captain, M.C.; Alvin R. Megahan, Major, M.C.; Gordon S. Owen, Captain, M.C.

Fig. 1. Photograph of gangrene of finger tips resulting from frostbite.

line, but this does not often spread far into nearby viable tissues. The distal part remains black, dry and leathery. Less severe cases have only gangrene of the skin, the deeper structures remaining viable. Such toes cast off their dead shell after new skin has regenerated beneath it.

In contrast to these severe cases, the greater number do not eventuate in gangrene at all. Although most feet become anatomically normal after several weeks or months, many continue painful on weight bearing and sensitive to cold for an indefinite period. This report is not concerned with these lesser degrees of trench foot, which were not under our direct observation.

Most surgical cases had only distal parts of some toes devitalized and consequently required partial toe amputations. A small number lost all toes on at least one foot, and some lost one or more metatarsal heads as well (Table I). In a few cases, and these were usually severe ones (Figs. 1 and 2), trench foot was associated with leg wounds, such as a compound fracture or trauma to the femoral artery. In these circumstances, the soldiers had been lying on cold ground, from several hours to as long as 3 days.

Preoperative routine. The patients were given every chance to improve on conservative manage-

Fig. 2. Trench foot gangrene of distal portion of foot associated with compound comminuted fracture of femur.

ment. Active and passive exercises were given to the toes, many of which were atrophic and fixed in partial flexion. The patients were instructed as a group forcefully to flex and extend their toes—using their fingers to do it. This ward exercise, done several times daily, was combined with a lanolin lubricated massage to relieve the dry scaling frequently seen on these toes. Adequate passive and active motions tended to free adhesions about tendon sheaths and joint capsules, and many toes that would otherwise have had to be amputated before shoes could be worn, were thereby saved. In addition to exercises to loosen up fibrotic toes, active foot and ankle exercises were employed to prevent contracture of the tendo achillis and gastrocnemius soleus muscle group with consequent talipes equinus and pes cavus. Other frequently employed types of physical therapy, and whirlpool baths, in particular, have proved of no use in most cases.

The usual preoperative laboratory work included smears and cultures taken at the demarcation line. Not only was the bacteriological flora identified but, if applicable, penicillin sensitivity tests were reported at the same time. This entailed only an additional day's delay in receiving the report. Of 95 cases in which penicillin sensitivity composed part of the bacteriological study,

TABLE I.—DISTRIBUTION OF GANGRENE

	Cases
Partial gangrene of toes	197
Loss of all toes of a foot at proximal joint	11
Loss of one or more metatarsal heads	32
Loss of all metatarsal heads	35
Loss requiring transfer to center for "below knee" amputation	2
Gangrene with loss of heel plantar skin	6
Gangrene of fingers (Fig. 1)	3

TABLE II.—BACTERIOLOGICAL FLORA

	Cases
Resistant to 1 unit penicillin per c c	23
Hemolytic <i>Staphylococcus aureus</i>	7
<i>Bacillus coli</i>	
Susceptible to 1 unit penicillin per c c	15
Nonhemolytic corneobacterium	9
Hemolytic diphtheroid corneobacterium	10
Beta hemolytic streptococcus	

Fig. 3. Left, This great toe had formerly been black up to the metatarsophalangeal joint. The gangrene was only superficial and was cast off like a glove. (Note the transverse ridge on the nail.)

Fig. 4. Thin grafted skin is unsatisfactory permanent covering for end stumps. It ulcerates when weight bearing is attempted.

it was found that most wounds harbored at least 2, and often 3 or 4 organisms. Table II shows the spread of the flora.

The trench foot cases were routinely given a preoperative injection of 50,000 units of penicillin intramuscularly when they received preoperative medication. The routine use of sulfa drugs was not encouraged because of the needlessly increased risk of reactions associated with their use.

Roentgenograms of the involved foot were requested as part of the preoperative work.

Surgical principles. Since no clear cut precedent had established all the surgical principles concerned in the surgical treatment of trench foot, the general plan of treatment underwent evolution as experience accumulated. For instance, it was deemed wise to delay surgery until all possible spontaneous recovery had occurred. Many soldiers with toes black on admission here, progressed so favorably on conservative care, that within 2 to 4 months they lost the gangrenous tissue (Fig. 3). A considerable number of these soldiers now have their toes and feet intact. Had they been operated upon early, they would have suffered an unnecessary loss which, originally, could not have been well prognosticated. A few soldiers have been admitted here who were subjected to early amputation elsewhere, and they usually seemed to present greater loss than one would expect should have occurred.

Fig. 5. Above, A flap of normal weight bearing plantar skin and subcutaneous tissue is required as cover for good end stumps.

Fig. 6. All metatarsal heads have been sacrificed to provide good end stumps from plantar skin. This soldier runs and walks surprisingly well.

Another surgical principle that emerged with experience, was concerned with the inadvisability of depending upon grafted skin to cover stumps of feet. The advantages of retaining all possible foot length are obvious, but the attempt to accomplish this by grafting skin to an exposed stump results in a poor foot. Such a foot with an end stump covered with thin skin has no subcutaneous tissue to protect the superficially palpable bone ends (Fig. 4). Weight bearing

Fig. 7. Skin traction apparatus to assist in closing skin flaps and in preventing skin retraction.

stretches this unpadding skin, which is of low vitality, and it is prone to break down and become the site of an ulcer. Several such patients received here were submitted to corrective surgery. Where good plantar skin flaps, having adequate subcutaneous tissue, were brought up to cover end stumps, good functional feet were obtained. This plantar type of skin and subcutaneous tissue is highly specialized for weight bearing and when pads of it cover bone ends, the stumps are well protected against trauma.

In order to gain this type of end covering pad when gangrene has extended proximal to the webs of toes, it was sometimes necessary to foreshorten metatarsals by removing their heads. Contrary to general surgical opinion, removal of the first metatarsal head, or the fifth—or any—or all five, does not usually too seriously handicap function of the foot. As a surgical principle these heads were removed without hesitation, if that was necessary to obtain enough skin and subcutaneous tissue, particularly from plantar flaps, to cover stump ends (Figs. 5 and 6).

Another surgical principle concerned the method of obtaining closure of the stump. All of these feet were infected, in the sense that bacteriological smears and cultures could be obtained from the demarcation line, but few were chronically inflamed in the area of proximate viable tissue. At first, true guillotine type amputations were done. These required secondary surgery when prolonged skin traction was not completely successful, and the resultant secondary surgery meant additional loss of toe or foot length. Con-

sequently, it became general practice, even on toes, to leave generous flaps to cover the stumps. Where possible, these flaps were fashioned from the plantar surface. Secondary closure, at first done on the fifth day if the stump was clinically free from infection, was advanced with increasing experience, to the fourth and third days, until ultimately, primary closures were done. This was safe because of the postoperative routine presently to be described.

In some early instances when the first metatarsal head was removed, the sesamoids were allowed to remain. They became secondarily chronically infected and were the source of draining plantar sinuses. Even in some disarticulations in which the metatarsal heads were not removed, this was still true. Because these sesamoids had to be removed later, it became a policy to remove them carefully at the original operation, except in those cases in which the metatarsal head was allowed to remain, and in which, further, the sesamoids were safely deep from the edge of the plantar skin flap and clearly surrounded by viable tissue. Under these latter circumstances, they were not disturbed, and none so selected gave further trouble. In fact, they no doubt were useful in helping make up the normal bulk of the resilient pad beneath the first metatarsal head.

An additional surgical principle that frequently proved helpful in taking strain off a suture line and preventing retraction of skin, or occasionally in aiding the approximation of a secondarily infected stump, was skin traction (Fig. 7). Traction was provided by gluing a short length of stockinet on to the foot with ace adherent. Counter traction was obtained by suspending a spring metal hook over the stump and anchoring this hook into a plaster boot. The boot extended to just below the knee, and held the foot at a right angle. This boot loosely covered much of the stockinet but was quite free from fixed contact with it. A spreader with eight to ten rake teeth was hooked into the stockinet and suspended from the boot hook by means of a short length of rubber tubing under considerable tension.

In a few instances having short foot stumps, no additional plantar skin was available to bring up over stump ends. Some of these feet with good ankle motion and adequate plantar walking surface were not condemned to amputation. Instead, full thickness skin flaps were employed to cover the stumps. Either cross leg flaps or jumped tubes were used. Similar plastic procedures were required to cover a few denuded heels.

Additional operative procedures, usually thought of in association with trench foot, have not been

done here. There has been no place for either sympathetic block or sympathectomy.

Surgical technique. All amputations were done under pentothal-oxygen anesthesia. Incisions were made just proximal to the typically narrow zone of reaction on the plantar skin. A longer plantar flap and shorter dorsal flap made possible a dorsally placed scar line. Because of lessened tissue viability, together with the bacteriologically positive conditions present, it was a principle not to place buried sutures, absorbable or otherwise, within the amputation stump. As a matter of fact, although bleeding was usually brisk, it was practically never necessary to ligate a vessel.

The periosteum was left undisturbed prior to bone resection. The additional trauma to surrounding soft tissues involved in freeing this periosteum did not aid in the kindly healing of tissues which were, at best, handicapped in viability. Perhaps worth recording is the impression that these stumps and flaps were sometimes not free in their bleeding; that frequently the cancellous bone, on being sectioned, stayed white and free from oozing; that the cortex was usually extremely soft, but at other times was normally dense and brittle and, that now and then, the digital arteries were grossly thrombosed. Regardless of these not so favorable findings, the wounds healed kindly, if somewhat slowly. Closure was either primary, or delayed 2 or 3 days, depending on the gross appearance of the skin flaps. Sutures were fine black silk, sparingly used.

Postoperative routine. Following operation, saline dressings were used when a delayed primary closure was being done, and, simple dry dressings for primary closures. Sutures were allowed to remain up to 6 days in the presence of mild postoperative redness and up to 10 or occasionally 12 days if the skin was entirely free from reaction. Sometimes, when it became necessary to remove sutures before healing was complete, adhesive butterflies were useful, but, if left on too long, maceration and undue pressure effects were found beneath the tape. For large stumps in these circumstances, the traction cast previously described was useful.

Postoperatively, penicillin was given in 25,000 unit doses intramuscularly every 3 hours for at least 300,000 units and frequently for 5 or 6 days, or until the sutures had been removed.

The patients were kept off their feet quite a bit longer than one might think necessary. Even after sutures had been removed and the toes or foot stumps seemed well healed, a soldier frequently stubbed a toe, and this sometimes developed a reactive hyperemia or even an acute

Fig. 8. Prosthesis built on insole for use in standard type shoe.

cellulitis which was slow to resolve. It seemed the tissues lacked resistance to trauma, and being traumatized, lacked resistance to infection. For this reason, a policy of prolonged observation was maintained after definitive treatment had been completed. During this time, of course, the same group physical therapy employed preoperatively, was resumed in normally convalescing cases. Each patient was required to complete 30 days without incident, either on convalescent furlough at home, or at the convalescent hospital, before being given a Certificate of Disability Discharge.

A simple prosthesis has been evolved for all patients who have lost three or more adjacent toes, and for all patients who have lost the metatarsal heads (Fig. 8). Basically, it is a shoe insole, often combined with a longitudinal arch support, and having built on to it a felt block to fill in the space between the foot stump and shoe tip. That part of the felt block nearest the stump is faced with lamb's wool. The rest of the block is covered with thin soft kid leather. In those patients not requiring arch supports, insoles are of thin leather. To prevent the shoes from flexing too much on weight bearing, the tips of the soles are opened and a flat spring steel insert is slipped lengthwise into the soles. By means of these prostheses, the owner can purchase standard shoes, and can wear them without complicated alterations. Using these prostheses, wearers walk more comfortably and more naturally than they do without them.

Complications. In about 20 per cent of the cases a slight local redness appeared postoperatively. This transient cellulitis was usually not severe enough to require the removal of sutures,

and penicillin usually seemed to bring it quickly under control. When it was inadequate, one of the sulfa drugs sometimes had to be substituted. The cellulitis then promptly disappeared.

Not to be confused with this mild postoperative cellulitis was a different phenomenon of rather similar appearance. When these soldiers began to regain use of their feet, the tissues about the stump ends not infrequently became quite red and angry looking. This condition was associated with neither pain, heat, or swelling, and on resting for a few hours, it completely disappeared. This reactive hyperemia, in response to trauma, as brought about at first by weight bearing, tended to lessen and finally disappear as the days went by. It proved to be of no serious import, but when present, walking was somewhat curtailed.

Except for the mild local cellulitis previously mentioned, postoperative difficulties were few. There were 23 instances of infection with demonstrable pus. These included 4 cases of acute lymphangitis and 1 lumbrical space abscess. Chronic osteomyelitis was surprisingly rare. There were only 5 cases, 1 of these being associated with trench foot in a compounded injury.

Varying types of dermatitis were troublesome in 9 cases. Among these, a temporary generalized urticaria due to penicillin occurred twice, a localized staphylococcus pyoderma was present twice, and a chronic eczematoid dermatitis once. This latter involved all the toes, and the skin was chronically reddened, dry, and scaly.

In these surgical cases, sweating was no problem. In trench foot reports by some, much emphasis has been placed on cold sweating feet. When it is recalled that this phenomenon is part of the characteristic picture of "battle fatigue" and that sweating is frequently present in soldiers who do not have trench foot, and further, that many soldiers with trench foot also have "battle fatigue," one can hardly specify sweating feet as exclusively part of the trench foot picture. In these cases of most severe trench foot, if gangrene is any criterion, there was no more sweating than would be found among a like number of soldiers convalescing from other types of injuries.

Psychologically, the loss of some or all toes, or even the distal portions of one or both feet, has presented no problems that have not been satisfactorily mastered. Probably this is because the soldiers are treated in wards where they are surrounded by others with surgical trench foot.

Disposition. Final disposition has been made on most of these cases. None were returned to duty whose feet were not anatomically and symp-

tomatically normal. Therefore, all here reported either have been given certificate of disability discharges, or will be given them when they have reached maximum benefit of hospitalization. Before being discharged, information regarding future care of the feet is given in group talks. All are told that they will continue to improve gradually for as long as 2 years, but that at first they must take measures to guard their feet from undue trauma.

SUMMARY

From a total of 4,892 soldiers with trench foot admitted, an experience with 264 cases requiring surgery is recorded. Many additional patients had only a temporary superficial gangrene of the skin of the toes, which spontaneously recovered.

Most patients lost only parts of several toes. Eleven, however, lost all toes of at least one foot, and 32 lost some or all the metatarsal heads as well. With increasing experience, it was found useful to adhere to certain surgical principles. Surgery was delayed until all possible spontaneous recovery had occurred. This saved toes and feet. Grafted skin was found unsuitable for covering stumps. The advantages of covering a stump with a flap of normal weight bearing type plantar skin outweighed the advantages of retaining metatarsal heads. Contrary to general surgical opinion, removal of some or all metatarsal heads was found not too seriously to handicap the function of the foot. At operation, the disadvantages of tying bleeders and of employing a periosteal elevator are mentioned. Sesamoids were removed only when infected or when it was expected they would become infected and cause a postoperative draining sinus. When penicillin was routinely administered, both preoperatively and postoperatively, it was found practicable primarily to close the skin flaps fashioned at the time the gangrenous toes were removed. Infection was rare, and there was no correlation between the frequency of infection and the types of infecting organisms. An effective method of skin traction was sometimes used to help take the strain off suture lines and prevent skin retraction. A postoperative reactive hyperemia on a traumatic basis is described and contrasted to postoperative cellulitis due to infection. Postoperative complications were relatively infrequent. Preoperative and postoperative active exercises helped to prevent shortening of heel cords and correct fibrotic contracture of toes. A prosthesis designed to be part of a shoe insert, often combined with a longitudinal arch support, is described.

THIOURACIL WILL NOT REPLACE THYROIDECTOMY

ARNOLD S. JACKSON, M.D., F.A.C.S., Madison, Wisconsin

AFTER 2 years of clinical experience with thiouracil in the treatment of hyperthyroidism, it is my belief that this drug will not replace thyroidectomy, despite the enthusiastic reports accorded it in the literature. Such claims that thiouracil is the method of choice in the treatment of toxic goiter are unscientific. The facts were better stated in an editorial in the *Journal of the American Medical Association*, September 16, 1944, as follows: "Whether or not thiouracil will prove to be a satisfactory substitute for surgical treatment of toxic goiter cannot be stated on the basis of present limited experience. The drug promises to be of great value in cases in which operation is inadvisable or contraindicated."

Thiouracil will never replace thyroidectomy in the large group of cases commonly designated as multiple toxic adenomas or adenomas with hyperthyroidism. Whether one chooses to designate this group of cases as a distinct clinical entity after the method of Plummer or whether they be considered together with exophthalmic goiter as merely a variation of the same disease makes little material difference. Adenomas are essentially neoplasms and are prone to affect the patient in many other ways than through their toxicity and, as such, require surgical removal. One should surely hesitate to advise the relief of hyperthyroidism in a case of this kind and then see the patient later succumb to a malignancy or the effects of an intrathoracic goiter. Consequently, fully 40 per cent of the so called toxic goiters have been eliminated from the category of successful treatment by thiouracil.

There remains the group of cases commonly spoken of as exophthalmic goiter (diffuse toxic goiter—Basedow's disease, Graves' disease, etc.). In this type much more investigation and study will be required before any considerable number of cases may be judged as cured. In a small series of 35 cases I would hesitate to say that any might be considered as cured judging from the short period of time they have been under observation. Furthermore, experience seems to favor the opinion that the majority of cases of this type should not be subjected to treatment with thiouracil on the basis of our present knowledge of the

drug. In a recent discussion of the subject mention was made of the fact that 27 fatal cases of agranulocytosis occurring from the use of thiouracil had been reported up to that time. This is an exceedingly high mortality in comparison with that for the operative treatment of the average case of exophthalmic goiter in the hands of the experienced thyroid surgeon. Patients residing at a distance find it inconvenient to report for frequent blood counts, and thus is augmented the possibility of the development of agranulocytosis.

If the health of the average patient suffering from exophthalmic goiter may be restored by surgery within a few weeks and he resume his usual duties with a normal metabolism, there seems little justification in subjecting him to months or years of therapy with an admittedly dangerous drug. Furthermore, we agree with Lahey¹, who is of the opinion that since thiouracil in no way changes the histologic picture of exophthalmic goiter, it is not a drug to be employed as a curative agent.

There are, however, certain indications in which the risk of using thiouracil seems definitely justified in comparison with the risk of surgery. These indications previously indicated² might be enumerated as follows:

1. Advanced cases of multiple toxic adenoma in which there is no response to iodine.
2. Cases of toxic adenoma complicated by such conditions as myocarditis, fibrillation, hypertension, diabetes, and decompensation.
3. Cases of severe exophthalmic goiter in such patients as the very young, the aged, the debilitated, and the decompensated.
4. Cases of exophthalmic goiter in whom because of pregnancy, previous nerve injury, infections, or other diseases it may be desirable to delay surgery and yet not continue on iodine.
5. Cases of iodine-fast exophthalmic goiter.
6. Cases of recurrent or persistent hyperthyroidism.

Our experience in all these types of cases with thiouracil has proved encouraging. Probably the gravest risk in the surgical treatment of hyperthyroidism has been brought under control, namely, the advanced cases of toxic adenoma in which a two stage thyroidectomy has usually

been required to safeguard the patient. After several weeks of preparation with thiouracil, I have successfully performed a one stage thyroidectomy in 12 of these cases. Likewise, in several cases in which the systolic blood pressure was in excess of 225 and in which the threshold of cardiac reserve was small, thiouracil has appeared to reduce the risk considerably.

There has been an opportunity to use the drug in children in only 3 patients having exophthalmic goiter. An 11 year old child was on treatment for 13 months and now shows an unfavorable response since the drug was withdrawn 3 months ago. Another child of a similar age was kept on the drug for several months with unsatisfactory results and then underwent a successful two stage thyroidectomy. A third child is now on treatment with insufficient time elapsed to draw any conclusions.

An interesting case is that of an 18 year old girl who sustained a bilateral adductor laryngeal paralysis, the result of a thyroidectomy performed previous to her admittance to the Jackson Clinic on April 1, 1943. In December, 1943, treatment with thiouracil was started because she

had had a recurrence of the hyperthyroidism and because the risk of surgery was out of proportion to the danger of using the drug. Three months ago (July, 1945) therapy was discontinued, and so far the patient has retained her weight and a normal metabolism.

At the present time I have under observation a woman who is 8 months pregnant and who has a moderately severe exophthalmic goiter. In the past I have performed thyroidectomy in a series of 15 cases of this type with no mortalities in either the mother or child. However, in none of these cases was the patient so near to term, the average being 5 months. Consequently, it seemed inadvisable to carry these patients along on iodine until the time of delivery because of the danger of inducing an iodine-fast state. The case now under treatment has been on thiouracil for 2 months and is in excellent condition. Probably thyroidectomy will be performed about a month after delivery.

The term "iodine-fast" exophthalmic goiter was suggested by the writer at the 1931 meeting at Denver of the American Association for the Study of Goiter.¹ At the time it was described as

tive response to thiouracil and Lugol's solution. First thyroidectomy; very little reaction. Six months later operation, basal metabolic rate, +11 per cent, weight gain.

Fig. 6. No. 124-717. Case of multiple, toxic adenoma of thyroid with diabetes. Prepared with thiouracil for thyroidectomy.

a new syndrome, one might even say a distinct clinical entity, in which all the classical signs and symptoms of exophthalmic goiter may be absent. Cases are seen in which there is no thrill, no bruit, no tremor, no exophthalmos, and no weight loss. In fact, these patients may even gain in weight. The gland, instead of being firm, smooth, and symmetrical, is nodular and irregular from prolonged, partially controlled hyperthyroidism. There is no clinical response to iodine. Surgeons have come to look upon these cases with considerable apprehension and to consider the surgical risk as comparable to that in advanced cases of multiple toxic adenoma. Usually a two stage thyroidectomy has been required and even then the reaction that followed a lobectomy was often as severe as in a similar operation performed in the era previous to the use of Lugol's solution. Thiouracil has proved a boon to the patient and surgeon alike in the treatment of these patients. In our clinic 5 patients with this type of thyroid disease have been operated upon—a primary thyroidectomy being done after several weeks of preparation with thiouracil. All of them showed no more than the average reaction to operation.

Those working in the field of thyroid surgery have never felt that thyroidectomy was a method of treatment of exophthalmic goiter. It speaks of a cure in this disease, but it is the treatment of cancer, tuberculous disease, because of the well known tendency of the disease to recur months or years after apparently successful thyroidectomy. It has been the hope of all who have been concerned of hyperthyroidism that there would be a more satisfactory method of treatment uncovered. When Plummer first suggested the use of Lugol's solution, it was thought some that this might effect a cure in cases of recurrent or persistent hyperthyroidism. It has proved to be true, but it has not eliminated its use for the treatment of many such cases. Crile advocated thyroidectomy as a method of treatment. This operation was often followed by a reaction which fall into dispute with the medical procedure.

Now thiouracil is brought forth as a method of replacing thyroidectomy in the treatment of hyperthyroidism. Chemotherapy may prove to be the solution to the successful treatment of hyperthyroidism, cancer, and many other diseases, but as yet it has not attained the success of the sulfonamides in the infectious conditions. It now appears that thiouracil has been under sufficient clinical investigation to state that it will supplement but not supplant thyroidectomy in the treatment of hyperthyroidism. That it may effect a cure in incipient and milder cases of exophthalmic goiter is still to be proved. It has already proved a most valuable adjunct to surgery in the treatment of hyperthyroidism. There is every hope that thiouracil will give way to some less toxic but still more efficacious drug in the treatment of hyperthyroidism. Its discovery is a step forward, and those dealing in the problems of hyperthyroidism are greatly appreciative of investigators who have made thiouracil available.

CONCLUSIONS

Two years of study of the use of thiouracil in the treatment of hyperthyroidism have shown that it will not replace thyroidectomy.

Thiouracil will supplement but not supplant surgery in the treatment of toxic goiter.

It has been noted that 27 deaths have already been reported as occurring following the use of the drug.

Thiouracil cannot effect a cure in toxic adenoma.

Six types of cases are listed in which thiouracil has proved of definite value.

Thiouracil may prove of curative value in the treatment of exophthalmic goiter, but sufficient time has not yet elapsed to warrant such a conclusion.

While the use of thiouracil has proved an important forward step in the treatment of hyperthyroidism by chemotherapy, it is desirable that a less toxic drug be discovered.

FEEDING TUBE STENOSIS OF THE LARYNX

PAUL H. HOLINGER, M.D., F.A.C.S., Chicago, Illinois, WILLIAM J. LOEB, M.D.,
Cleveland, Ohio

THE indwelling nasal tube, employed chiefly for gastric decompression or for feeding purposes, is so widely used that it is important to draw attention to the possibility of laryngeal damage it may produce. Instances of this complication are relatively uncommon, but, when they do occur, constitute a difficult therapeutic problem. The indwelling tube in the cases to be discussed was the cause of erosion of the anterior esophageal wall at the level of the cricoid cartilage, with subsequent inflammation of the laryngeal cartilages and their ultimate necrosis. This pathological sequence led to a collapse of the airway and a severe, chronic laryngeal stenosis which required tracheotomy and months or years of subsequent treatment. This discussion is presented to call attention to this serious complication and to stress the predisposing as well as exciting etiological factors responsible for it. Through an understanding of these factors, the recognition of early symptoms and the prompt execution of simple corrective measures will prevent the development of this type of chronic laryngeal stenosis.

PRESENTATION OF CASES

CASE 1. N.G., a 52 year old white Polish housewife, was seen first at the Research and Educational Hospital in March, 1939. She was found to have diabetes mellitus and a large, cystic, firm thyroid without toxic symptoms, but with definite compression symptoms. Her basal metabolic rate was +11 and her fasting blood sugar was 333. She was placed under medical management until August, 1939, when a subtotal thyroidectomy was performed. She had no hoarseness or breathing difficulties following this procedure, and her recovery, while slow, was uneventful. In April, 1940 the patient developed severe pain in the right lumbar area which radiated anteriorly to the right lower quadrant and into the vulvar area. The pain was severe, constant, sharp, and was associated with nausea and vomiting. The pain apparently was an aggravation of a dull pain of which the patient had been complaining for 4 months. On admission her temperature was 101.6 degrees; white blood count, 19,300; and her blood sugar was 250 milligrams per cent.

A tentative diagnosis of an appendiceal abscess was made, and an indwelling duodenal tube was introduced April 17, 1940. The patient was very intolerant of the tube because of discomfort and pain, and made frequent attempts to remove it manually or by vomiting. It was left in place for 4 days. No abdominal surgery was per-

formed as the diabetes was out of control although she received adequate insulin and intravenous glucose therapy. By the time the tube was removed the diabetes had been controlled and the abdominal pain had almost completely subsided. However, the patient complained of an increasingly severe sore throat which began at the time the tube was introduced and continued even after it was removed. She would take only liquids, refusing solids because of pain on swallowing. Hoarseness developed after the tube was removed. The tenderness in the right lower quadrant gradually decreased, and her problem became one of respiratory difficulty. An indirect laryngoscopy on May 4, 1940, revealed considerable edema of the vocal cords; it was difficult for her to make audible sounds.

By the sixth week of hospitalization, pain in the right side of the neck and respiratory difficulty had increased markedly. The larynx was more edematous, especially posteriorly; the arytenoids were large and boggy with edema, and the motility of the cords was impaired by the edema, but no paralysis was present (Fig. 1). A tracheotomy had to be done June 3, 1940. Clinical improvement was slow and x-ray films of the neck demonstrated a progressive destruction of laryngeal cartilages as well as a spread of the laryngeal inflammatory process to the soft tissues of the retroesophageal space (Figs. 2 and 3). Chemotherapy was employed, but because of the patient's generally poor condition and the difficulty in controlling her diabetes, extensive surgery of the larynx seemed contraindicated at this time. Purulent drainage into the larynx persisted for 2 months before gradually subsiding. Subsequent treatment has consisted of two series of laryngeal dilations under direct laryngoscopy. At present the patient still wears her tracheotomy tube, but can keep it corked for several hours at a time (Fig. 4). Her voice is husky but audible.

Thus, this patient, a diabetic, had a feeding tube in place for 4 days during which time it caused discomfort, sore throat and pain, and vomiting had occurred. Laryngeal edema subsequently developed, and a tracheotomy became necessary 7 weeks following removal of the tube. The patient now has a chronic laryngeal stenosis which is responding slowly to treatment.

CASE 2. Mrs. E. B., white, 48 year old housewife. In September, 1940 this patient had a gastroenterostomy and a stormy convalescence followed. A nasal tube was in place 17 days. During part of the time the tube was in place the patient complained of a severe sore throat and pain extending into her ears. This subsided temporarily and the patient was discharged from the hospital. The pain recurred in 2 weeks and became very severe; it was followed by laryngeal edema which increased gradually. Four weeks after leaving the hospital readmission became necessary because of respiratory distress, and an emergency tracheotomy had to be done 24 hours later. Improvement was gradual, and the patient was extubated 5 months later. During the ensuing 3 years dyspnea with exertion was

larynx was impaired because of cicatricial contractures, but the configuration of the vocal cords was essentially normal. A second tracheotomy was done in March, 1944, and the larynx dilated repeatedly by direct laryngoscopy. The tube was removed in September, 1944, after the patient's

OBSERVATIONS ON A CONCEPT OF INGUINAL HERNIA REPAIR

WILLARD BARTLETT, Jr., M.D., F.A.C.S., Captain, M.C., U.S.N.R., St. Louis, Missouri

THERE is once more a rising tide of speculation among surgeons as to the actual results of the traditional methods of inguinal hernia repair. There is coincidental reflection of dissatisfaction with such results in the continuing publication of alternative methods of radical revision of the abdominal wall. Statistics are usually furnished in an effort to show that fewer failures have occurred with the recommended technique than in any other series cited by their author from the literature. There is nothing novel about this situation, for in an exceedingly interesting article, to which further reference will be made, Pitzman stated in 1921: "The size and eudlessness of the stream of inguinal herniotomy technique raises the strong suspicion that something is fundamentally wrong."

At the time of going on active duty in the Medical Corps, the present writer had a concept of inguinal hernia, which though by no means original, was unorthodox. A rather concentrated experience with this disorder in naval personnel has strengthened his belief in the validity of this concept and in the necessity of including certain technical steps in any plan for achieving correction. It has been impressive to observe the development of a similar point of view among many thoughtful surgeons who, entering service with a more traditional concept of inguinal hernia, have also had the opportunity of daily exploration or observation in this field. In the 20 month period between February 15, 1944, and October 15, 1945, 1,398 operations were done for primary inguinal hernia, 89 operations for recurrent inguinal hernia, and 11 operations for femoral hernia at the United States Naval Hospital, Naval Training Center, Great

Lakes, Illinois. Due to the exigencies of the service, tabulation of the operative findings has not been completed, but reference will be made in this paper to observations on which those of us who had duty there during that period are in agreement. Sliding hernia will be excluded from consideration.

A critical review of the literature for the last 10 years leaves the writer with one conviction which is very disappointing (his own position as unorthodox having been stated): there is no published evidence that in any group of patients with inguinal hernia operated on by the Bassini technique (including such variations in the disposal of the external oblique aponeurosis as are usual), there would have been fewer failures had another operative procedure been chosen! This conclusion is derived from the fact that no standards of reporting have been agreed on. The converse of the first conclusion is that there is no statistical evidence that a surgeon advocating one of the suggested alternatives to the Bassini would have had poorer results had he used the latter. The fact is that far more complete data are available as to the results of operations done by the Bassini method than of any, including that advocated by the writer, intended to supplant it. Those who may question these assertions will find their answer when they seek to apply to the published statistics of any given procedure the best facts available as to the relationship between the intervals (in years) after operation and the percentages of recurrences. Burdick and Shelley (16, 17, 18) in analyzing their own recurrences detected in yearly follow-up examinations, found that in 284 and 210 traced recurrences, respectively, less than one-half were found in the first year and approximately two-thirds in the first 2 years; about 83 per cent were detected in the first 5 years in each series and the remainder thereafter. It happened that the overwhelming majority of pa-

The views expressed herein are those of the author and are not to be construed as those of the Bureau of Medicine and Surgery or of the Navy Department.

Fig. 6. Case 3. Lateral view of the neck showing the postcricoid thickening and narrowing of the airway at the level of the cricoid cartilage. The principal area of stenosis was immediately subglottic.

airway was tested by plugging the tube night and day for several days.

In this case an extremely ill patient had a nasal stomach tube in place for 17 days during which time a sore throat and pain in the neck and ears developed. Symptoms improved following removal of the tube, only to recur in 2 weeks and increase in severity to a degree requiring tracheotomy. This was done 1 month after removal of the feeding tube. Eventual subsidence of the process resulted in a chronic laryngeal stenosis for which a second tracheotomy had to be done to permit adequate treatment. At present she breathes freely without a tracheotomy and has a clear voice.

Case 3. Mrs. E.A., secretary, white, 43 years of age. This patient had had four operations for gall-bladder disease between 1926 and 1940. In December, 1940, a fifth operation was performed and a nasal tube was left in place 7 days. The tube annoyed the patient considerably, causing a sore throat and considerable gagging, but the patient states she did not vomit. Symptoms improved following removal of the tube, but the sore throat became worse a week later, and gradually localized as severe pain deep in the neck, aggravated distressingly with swallowing. The patient developed hoarseness and then a complete aphonia 3 weeks later. Dyspnea began suddenly one night in February, 1941, and an emergency tracheotomy was done. Attempts to extubate her subsequently were unsuccessful. The patient was referred to St. Luke's Hospital in August, 1941, for laryngeal examinations. At this time the stenosis of the larynx was almost complete. The true cords could not be satisfactorily exposed because of marked anteroposterior compression of the larynx. Small bougies were

passed through what appeared to be the laryngeal aperture, but they met with considerable resistance. By means of laryngeal dilators a definite lumen was re-established and the patient could then phonate again by manually closing her tube. The examination demonstrated that the principal area of stenosis was immediately subglottic (Fig. 6). Dilatations were carried out at frequent intervals but the larynx never remained open sufficiently to permit removal of the tube. However, a valve tube was substituted for the original tube, and the patient is now able to speak well with the valve tube without manually closing the tube. At present she holds an important executive position and carries on all conversation without difficulty.

In this case the nasal stomach tube was in place 7 days and caused a sore throat and gagging, but no appreciable pain. After its removal, pain, hoarseness, and later aphonia developed. Approximately 6 weeks elapsed from the time the feeding tube was removed until the tracheotomy had to be done. The patient now has a chronic laryngeal stenosis and is wearing a valve tracheotomy tube. She refuses further surgery because she has a satisfactory functional result.

CASE 4 A.M., 57 year old white female entered the Research and Educational Hospital on April 16, 1940, complaining of lower abdominal pain of 8 weeks' duration and persistent vomiting of 3 weeks' duration. The abdomen was distended with fluid, and rectal examination revealed a hard, fixed mass anterior to the rectum. Tumor cells were found in fluid removed by abdominal paracentesis. An exploratory laparotomy done 3 days after admission demonstrated an extensive carcinomatosis. Gastroenterostomy was done because of almost complete obstruction of the pylorus by the tumor. A stomach tube had been inserted when the patient entered the hospital and it remained in place for 5 days. It was then removed, and reinserted three times during the following 6 days; it was always tolerated poorly. The entire surgical wound opened on the eighth postoperative day. Reinsertion of the stomach tube at this time was associated with considerable trauma. The tube was withdrawn in an hour because gastric contents were not recovered. The overzealous attempt to insert the

tube resulted in a perforation of the esophagus and the patient expired 3 days later of the combined effects of the abdominal and mediastinal pathology. The primary tumor was found to be a papillary cystadenocarcinoma of the right ovary with extensive metastases. Postmortem examination of the esophagus demonstrated a deep ulcer 4 centimeters in length in the mucosa covering the posterior aspect of the cricoid cartilage (Fig. 7). The ulcer extended through all the walls of the esophagus and exposed an area of the cricoid cartilage which then made up the base of the ulcer. The cartilage itself was roughened and necrotic in this area. A recent perforation of the left pyriform sinus was found which led into a necrotic mediastinal abscess. The posterior cold erosion seemed older than the perforation and was distal to it. It was undoubtedly present before the final attempts were made to reintroduce the tube.

While this patient did not have a true feeding tube stenosis of the larynx, the postmortem examination of the larynx demonstrates the earlier phase in the process which ultimately leads to the development of stenosis. The stomach tube was in place a total of 6 or 7 days, always poorly tolerated. The presence of the ulcer across the slightly convex posterior surface of the cricoid cartilage is significant in that the cartilage is thus exposed to the action of bacteria as well as to the chemical action of regurgitated gastric contents.

DISCUSSION

Various types of rubber tubes have long been used for emptying the stomach or for feeding purposes. The type known as the Levin tube is usually employed, as it is of smaller caliber and more pliable rubber than the larger tubes. The continuous suction technique using this tube, as employed by Wangenstein (6), has resulted in widespread use of the Levin tube for relatively long uninterrupted periods. Passed through the nose, it descends into the pharynx, the laryngopharynx, the esophagus.

THE PROTEIN NUTRITION OF SURGICAL PATIENTS

THAT the surgeon should be concerned with the chemical and physiological aspects of his patients is now such a well known fact that it is trite to mention it.¹ There is no form of tissue repair in which the protein metabolism is not concerned. Protein metabolism is also concerned with resistance to infection, and resistance to poisons of various kinds. Serious protein depletion of the body tissues may be present in a large proportion of patients, particularly those who are markedly under weight. Such depletion may be the result of either acute or chronic illness. An acute illness may cause protein depletion with great rapidity, particularly in diarrheal diseases, burns, and major infections. Even in simple major fractures, net losses of protein representing a pound of tissue a day may go on for weeks.

Fortunately, methods to prevent or reduce these net losses are becoming widely available even for patients who cannot eat. Following the pioneer work of Elman,² intravenous protein hydrolysates and mixtures of amino acids for intravenous use have been found to be safe and practical, but the latter are not yet available for general use.

Parallel with this development, improved products for oral and intubation feeding have also become available. As one becomes familiar with the results following the use of such substances, the indications for their use become broader. The time has come when surgeons should become thoroughly familiar with the protein requirements of the normal and of the sick individual. In thinking of such requirements, one must be careful to think of the requirements in terms of optimum use rather than in terms of the requirements for bare existence. When time is available to improve protein nutrition before surgery, and when this time is used efficiently for this purpose, the reduction in postoperative shock and other complications is impressive. Under certain conditions indicated in a very suggestive paper of CoTui³ on gastroduodenal ulcers, improved protein nutrition may even abolish the necessity for surgery. When conditions do not allow time for preoperative repair of protein deficiency, postoperative repair at the earliest moment is very important.

Protein hydrolysates are not an efficient treatment of shock and should not be used during threatened or actual surgical shock. Whole blood is the method of choice in the treatment of this complication, with plasma

³CoTui, Wright, A. M., Mulholland, J. H., Galvin, T., Barcham, I., and Gerst, R. *Gastroenterology*, 1945, 5: 5-17.

Active treatment of laryngeal perichondritis once it has developed is exceedingly difficult and often disappointingly ineffectual. Chemotherapy, both the sulfa drugs and penicillin, should be administered, although none of these patients was in the acute stage when penicillin was available and consequently no clinical experience can be recorded. A tracheotomy is indicated, of course, if respiratory embarrassment becomes severe. Surgical drainage and sequestration of the larynx and its cartilages should be postponed, if possible, rather than attempted early, because the cricoid cartilage is the only complete ring in the trachea, and its loss results in a collapse of the airway. No laryngeal instrumentation is done during the acute phase of this condition. Subsequently, however, active laryngeal dilatation or surgical reconstruction of the airway is necessary in order to remove the tracheotomy tube permanently. On occasion it is possible to remove the tracheotomy tube after the acute edema and perichondritis subside. Stenosis may recur in such cases several months or years later as the scar tissue contracts (Case 2).

SUMMARY AND CONCLUSIONS

Severe laryngeal destruction occasionally results from the routine use of nasal feeding or gastric suction tubes. Fortunately this complication is rare; however, it is so severe when it does occur that it is important to be aware of the possibility of this complication and to recognize its beginning symptoms at once.

Four cases are presented. In 3, rubber nasal stomach tubes were used, 4, 17, and 7 days,

respectively, during which time the patients complained of discomfort due to the tube. Symptoms increased with sore throat, pain radiating into the ears, pain on swallowing, hoarseness, and finally dyspnea. Tracheotomies had to be done in three cases 4 to 6 weeks after removal of the stomach tubes. All developed severe chronic laryngeal stenoses. One has been extubated, one wears a valve tracheotomy tube, and the third is still under treatment. The fourth patient died as the result of extensive carcinomatosis and mediastinitis. Postmortem examination demonstrated the ulcer which had not as yet caused laryngeal destruction.

A review of the literature reveals 24 recorded cases similar to those herein described.

Treatment consists of removing or changing the position of a feeding tube if the patient complains of a sore throat, and especially if hoarseness or pain in the ears develops. Active treatment, aside from chemotherapy, consists of tracheotomy, drainage, and subsequent laryngeal dilatation or plastic repair.

surgeon a better degree of control over the patient's intake than any previous method of feeding. When such feeding is used for any condition other than burns or other than conditions where chronic salt depletion has been demonstrated, the amount of added salt should be greatly reduced or eliminated entirely. When a patient cannot or will not take this diet, tube feeding may be indicated and such a mixture may have powdered yeast and more amigen added because palatability is not a factor. A suitable formula for this consists of:

HIGH PROTEIN MIXTURE FOR TUBE FEEDING

		Cbh.	Prot.	Fat	Calories
Skim milk	3.0 L.	150	110	6	1094
Skim milk powder	200 G	75	60	6	503
Amigen powder	200 G	0	150	0	600
Valentine's liver extract	30 cc.	0	1	0	5
Brewer's yeast powder	30 G	11	14	1	113
Salt	15 G	0	0	0	0
		240	335	13	2413

The patients who need these types of oral or tube feeding also need vitamins, but over a long period of time probably do not need as high a dose of vitamins as the patients who are receiving parenteral protein feedings. Suggested oral daily doses for these patients would be vitamin A, 30,000 units; vitamin D, 3,000 units; ascorbic acid, 500 milligrams; thiamin, 20 milligrams; riboflavin, 12 milligrams; and niacin, 100 milligrams.

Charles C. Lund.

CONGENITAL HYPERTROPHIC PYLORIC STENOSIS

THE past quarter century has shown remarkable progress in the surgical management of most abdominal conditions and much of this seems to be due to our increased understanding of what Cannon has referred to as homeostasis. The

surgeon is now primarily an excellent physiologist and only secondarily a technician. The time and care which we all devote to the nutritional and electrolytic requirements of the body, both preoperatively and postoperatively, forcefully attest this fact.

Nowhere is this progress more clearly reflected than in the modern treatment of congenital hypertrophic pyloric stenosis, because nowhere else do we find such an extreme lability of this homeostatic mechanism. Man, who may be considered the most competent animal, produces the most helpless young, and this helplessness extends all the way from inability to avoid physical danger to inability to maintain a stable internal environment except under the most favorable circumstances. Obviously, therefore, when an infant of two or three weeks of age begins to vomit everything taken by mouth it will be but a short time before extreme dehydration and loss of electrolytes will so disrupt the delicately balanced biochemistry of his body that continuance of life will become endangered. While these facts are now so evident that to repeat them is almost tautological, it was but a few years ago that these acutely ill, dehydrated babies were subjected to emergency surgery. The surprising fact is that the operative mortality was only 35 to 40 per cent.

It seems to me that we were all very slow in realizing that these babies needed emergency "physiology" rather than surgery. They were desperately, albeit weakly, crying to us to replace their fluids and electrolytes so that they might survive this crisis which was threatening their existence. Having finally awakened to an understanding of these biochemical disturbances and having taken proper steps to aid the infant to correct them, it soon became obvious that the operation could be delayed several days, if necessary, until hydration was accomplished. Lowered mortality resulted.

and human albumin as effective agents to be used temporarily. Immediately after the danger of shock is over, protein hydrolysate or food may be given.

Plasma is being widely used in an attempt to repair protein deficiency. This is not an efficient method of treatment for this purpose. Whether money has to be paid for plasma or not, by the hospital or by the patient, plasma is a very expensive material. It has been calculated that the protein in plasma costs at least one dollar per gram. The corresponding price for lean hamburger steak in a generous serving of $\frac{1}{3}$ of a pound would be about twenty-five dollars. As a treatment for hypoproteinemic patients, one must also remember that plasma contains a great deal of sodium in the form of the original sodium chloride in the blood plus a generous amount of sodium in the form of citrate added to prevent clotting. When plasma is used in large quantities in the patient with true hypoproteinemia, increased edema and heart failure may well result.

Under conditions of severe burns or severe depletion from various infections or intestinal disabilities up to 400 or 500 grams of protein per day may be life-saving. Up to 150 grams per day of protein can be given intravenously in the form of hydrolysates or other similar preparations. Glucose may be and should be added to these hydrolysates because of its protein sparing effect. A formula suitable for many conditions has been suggested by Butler¹ and consists of 1 liter of amigen plus 300 cubic centimeters of 50 per cent glucose. This cannot be given in less than 4 or 5 hours because rapid administration causes nausea and vomiting, and if given into a moderate sized vein, seldom causes thrombosis. Three such injections a day will furnish 150 grams

of protein and 600 grams of carbohydrate. This amount of food represents 3000 calories.

Experience has shown that vitamins should be added to such a mixture in generous amounts for the patients who are sick enough to warrant this treatment. There is apparently very little wastage if 1 gram of ascorbic acid, 200 milligrams of niacin, 20 milligrams of riboflavin, and 20 milligrams of thiamin are given to such a patient at some time during each 24 hours.² Oral feeding or tube feeding to the hypoproteinemic patient or the patient in whom efforts are being made to avoid hypoproteinemia, should be in the form of mixtures of protein and carbohydrates with a minimum of fat. The following formula has been taken over periods of months by patients with burns which were so extensive that early grafting of the whole area was impossible.

HIGH PROTEIN MIXTURE FOR ORAL FEEDING

		Cbh	Prot	Fat	Calories
Skim milk	30 L	110	110	6	306
Skim milk powder	300 G	117	90	6	11
Amigen powder	100 G	0	75	0	600
Valentine's liver extract	30 cc	0	2	0	1
Salt	15 G	0	0	0	0
		227	277	12	318

This mixture makes up a large part of the food necessary for 24 hours and should be given in 8 ounce portions every two hours day and night. The patient taking this will have little appetite for any other food, but meat and carbohydrate food may be given immediately after at least three liquid feedings. Such a regimen avoids the very serious difficulty of the patient with a poor appetite choosing the more palatable but less important nutritional elements from an ordinary high protein diet tray and gives the

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

AS may be judged from the title, the two volume, 1200 page work *Surgical Treatment of the Motor-Skeletal System* by Baneroff and Murray¹, embraces the entire field of traumatic and non-traumatic orthopedic surgery. While created and fostered by the Division of Orthopedic Surgery at Columbia University, the collaborators number 43 men whose individual work and writings have made them outstanding in the fields of their special interests.

The majority of the authors are from the Eastern schools and clinics, but the overall impression is gained that no personal, group, or sectional viewpoint is stressed. Certain principles and methods of treatment are, of course, emphasized, because the author, in a number of instances, has originated them or has been responsible for their wide acceptance. For example, it would be expected that Dr. von Lackum would present the subject of scoliosis as he does, for much of our present management of this condition comes from the work of the New York Orthopedic Hospital Staff. Dr. Kite, who has made an art of the wedged cast treatment of foot deformities, naturally devotes more space to this method than to others. It is to be regretted that some of the articles were completed before the newer concepts of chemotherapy were generally accepted, but the editors have overcome this to some extent, in that they have written on chemotherapy as it applies to all the infections attacking the skeletal system. An example of this may be found in Dr. Beckman's chapter on osteomyelitis. This chapter is also an example of the thoroughness with which various conditions are discussed. Dr. Beckman draws on his wide experience in the Children's Surgical Service at Bellevue Hospital, so that an excellent background on osteomyelitis can be obtained by reading this chapter. Some of the newer concepts, more or less experimental at the time this work was completed, can be found in the section on chemotherapy.

It was somewhat disappointing to find nowhere in the book a chapter dealing entirely with the infections, injuries, and other conditions of the hand. One interested in looking up something in this field would be forced to seek through many chapters before finding the specific information required. The chapter entitled "Military Surgery" adds little to the usefulness of the book, but of course one may suggest that most of the important work that came out of the war is included other places.

¹*SURGICAL TREATMENT OF THE MOTOR-SKELETAL SYSTEM*. Edited by Frederic W. Baneroff, A.B., M.D., F.A.C.S., and Clay Ray Murray, M.D., F.A.C.S. Parts 1 and 2. Philadelphia, London, Montreal. J.B. Lippincott Co., 1945.

The general scheme of the volumes suggests that much thought was given to the presentation plan and this, plus the unusual activity of Dr. Murray, whose own views are many times expressed aptly if not sharply, makes it a fully adequate survey. The presentation of each subject is followed by a brief but comprehensive bibliography containing the citation of really important work that has been done in that particular field. Most reviewers will agree that there is a uniformity and smoothness of style throughout which is not found in the usual medical text by multiple collaborators, and this absence of encyclopedic jerkiness will be an incentive to become cover-to-cover readers of the two volumes. This was true of the undersigned, and it is something he has seldom before done.

It is impossible to discuss in detail all of the many chapters. The man interested in a particular problem at hand is sure to find complete and authoritative information. On the other hand the student, whose task it is to read for general rather than specific information will find his needs well filled. I know of no two volumes available now that would be more useful in the school years or afterward than this splendid work.

JAMES K. STACK.

EDITED by W. G. Barnard and A. H. T. Robb-Smith *Kettle's Pathology of Tumours*¹ is a most concise treatise. Since it was written for students, it is a didactic presentation with but little argumentation and few references to source material. Present day ideas in tumor fundamentals are adhered to generally. The development of this third edition (1946) is shown most strikingly if one compares certain sections in it with those of the first edition (1916). The sections on etiology, tumors of the lungs, and tumors of the nervous system have altered so much in these 30 years that they are entirely new concepts. Also in keeping with present times is the inclusion of a section on trauma and on occupation in relation to tumors. The book is richly illustrated by nearly 200 drawings and photomicrographs in approximately 300 pages of text.

HAMILTON R. FISHBACK.

THE two pocket books *Lecciones de cirugía*² are the first of a series to appear in the future. They are intended to give a written account of the Postgraduate Surgical Instruction as carried out on the

¹*KETTLE'S PATHOLOGY OF TUMOURS*. By W. G. Barnard, F.R.C.P., and A. H. T. Robb-Smith, A.F.A. (Oxon), M.D. 3d ed. London and New York: Paul B. Hoeber, Inc., 1946.

²*LECCIONES DE CIRUGÍA*. By Ricardo Finocchio. 1st and 2d series. Buenos Aires: La Prensa Médica Argentina, 1945.

At first these infants were given blood transfusions routinely as preoperative preparation. Later it was found that the parenteral administration of physiological solutions of glucose and saline produced the same result with fewer complications and less expense. Transfusions were then reserved for the infants which showed advanced dehydration, and were used in conjunction with the parenterally administered electrolyte solutions. Increased experience in this direction produced a further decrease in mortality.

Another factor which has improved the outlook for these babies has been the more prompt recognition of the disease. The typical and almost constant history of the infant who does very well for the first two weeks of life, then begins to regurgitate part of his feedings, then to vomit the whole feedings and finally to develop the characteristic projectile vomiting of bile free fluid, has become so well known to the medical profession that these babies are sent immediately to the hospital. They therefore arrive in much better condition and frequently they can be prepared in two or three days for surgical cure.

Usually, on arrival at the hospital, they are dehydrated, constipated, pass only small amounts of concentrated urine, and show visible peristaltic waves travelling across the abdomen. Palpation, especially when the stomach is empty, will reveal the pyloric tumor which is pathognomonic of the disease. Restoration of body fluids, electrolytes and, if necessary, serum proteins, is promptly begun, and, when restoration has been accomplished as demonstrated by clinical observation and the judicious use of laboratory tests, with probably major emphasis on the former method, surgery should be undertaken at that time.

The ultimate cure in every case seems to lie in the Fredet-Rammstedt operation, because it gives a permanent result and is very simple and rapid in its execution. We prefer a right rectus incision placed so high that the right lobe of the liver must be displaced upward to expose the pylorus. Great care must be used in dividing and spreading the hypertrophied pyloric musculature so that no damage to the underlying mucosa occurs. After careful layer-by-layer closure of the abdomen, the healing incision being effectively buttressed by the liver, we are reasonably insured against post-operative wound dehiscence.

After operation the baby should be kept in a room where the temperature is constant and where he is completely isolated from all other cases. Everyone who enters the room should wear a clean gown and mask. Extreme gentleness in handling the baby and the use of a small cane sugar pacifier at the time of wound dressings are of course, mandatory.

The surgical mortality in this condition at the present time is about 1.2 per cent. We are convinced that with proper preoperative, operative, and postoperative care, mortality should be about zero as far as the operation is concerned. Because the surgical mortality and morbidity are so low, we never consider prolonged medical treatment such as refeeding after vomiting, feeding by gavage, etc. The facts that ten days after this operation the baby is gaining weight and hungrily taking a generous evaporated milk formula and, that within three to four weeks, he has regained the position he would have held had he never had pyloric stenosis are convincing evidence of the efficacy of the operative method in the hands of the surgeon who will first carefully treat the baby and then skillfully treat the disease.

EDWARD J. DONOVAN

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

AS may be judged from the title, the two volumes, 1200 page work *Surgical Treatment of the Motor-Skeletal System* by Bancroft and Murray¹, embraces the entire field of traumatic and non-traumatic orthopedic surgery. While created and fostered by the Division of Orthopedic Surgery at Columbia University, the collaborators number 43 men whose individual work and writings have made them outstanding in the fields of their special interests.

The majority of the authors are from the Eastern schools and clinics, but the overall impression is gained that no personal, group, or sectional viewpoint is stressed. HAMILTON R. FISHBACK.

THE two pocket books *Lecciones de cirugía*³ are the first of a series to appear in the future. They are intended to give a written account of the Postgraduate Surgical Instruction as carried out on the

²*KETTLE'S PATHOLOGY OF TUMOURS*. By W. G. Barnard, F.R.C.P., and A. H. T. Robb-Smith, M.A. (Oxon.), M.D. 3d ed. London and New York: Paul B. Hoeber, Inc., 1946.

³*LECCIONES DE CIRUGÍA*. By Ricardo Finocchio. 1st and 2d series. Buenos Aires: La Prensa Médica Argentina, 1945.

service of Dr. R. Finochietto at the Hospital Rawson.

Each surgical paper deals with a case. The indications as to the type of operation are first discussed, and the selected procedure is given in full detail with numerous highly informative comments. The series will form an excellent source of information as to how surgery is practiced routinely by Dr. Finochietto and his resourceful coworkers.

*Páginas de cirugía*¹ is a 262-page book and is dedicated to Dr. E. Finochietto by the same workers mentioned previously in Dr. R. Finochietto's service. Fifteen different surgical procedures, including all types of surgery, are described. These works appeared in the *Prensa medica Argentina* (August 9, 1944) and are presented herein in a book form. F. F. REMY.

IT is impossible to review Cantor's *Ambulatory Proctology*² without being moved to comment on the author's viewpoint, highlighted as it is in title and preface. The author advocates and urges the performance of such procedures as extensive hemorrhoidectomy, repair of rectal prolapse and fistulotomy (to mention only three of many operations listed) on an office ambulatory basis. This attitude of mind which takes cognizance of the mechanical and physical equipment of the doctor's office, rather than the hazard to the patient, is unsurgical, unscientific, and dangerous to say the least. The practitioner would do well to pause and think of his patient before embracing such frankly dangerous practice.

If one does not take too seriously the author's mode of practice, the material encompassed in this volume is commendable. The discussion of the various proctologic ailments, though limited chiefly to management, is well presented. Steps to be taken in treatment are listed in definite sequence. There is a good section on pediatric proctology, which is missing in most recent books on the subject. Too great emphasis is placed on "tattoo" technique or what the author refers to as "tattoo neurotomy" in the treatment of pruritis ani, a method by no means applicable to a very large percentage of cases and certainly not available or practical for the average doctor.

There are many good illustrations. Especially well done are those descriptive of fistula in ano and fistulotomy.

One half of the book is devoted to medical diseases of the rectum and colon. Each chapter is concluded with an up-to-date and extensive bibliography.

THOMAS J. MERRAR.

THE book *Surgical Treatment of the Nervous System*³ edited by Bancroft and Pilcher is very sat-

isfactory, for it is simple; the descriptions are brief but adequate; and the twenty chapters have been contributed by seventeen different authors, so that there is considerable diversity. The plain truth is that neurosurgery, though a young and specialized field, does not lend itself well to an entire volume by a single author, for already among neurosurgeons themselves, there is some tendency to specialization or, at least, their talents and interests lie in different directions. Thus, one clinic may see large numbers of protruded discs, another, many sympathectomies, and still another may largely occupy its time with tumor surgery. And no civilian neurosurgeon can hope to match the sophistication of the younger men with army experience, with respect to peripheral nerves and cranioplasty.

Dr. Pilcher has picked leaders in all the fields he has covered. Their attacks on the subjects assigned to them have been orthodox and sound. While the book is perfectly understandable to the beginning student in the field, it is also of interest to the most experienced. It is reasonably well illustrated, and this reviewer found it as competent a book as exists on neurosurgery. ERIC OUDERGO.

THE book *Modern Management in Clinical Medicine*⁴ by F. Kenneth Albrecht is quite different from any of the usual textbooks of medicine, and is also different from the usual compendium of therapy. It attempts, and in great part succeeds, in being a handbook of the practice of medicine. It has an excellent professional attitude. Emphasis is placed upon the importance of a good case history as a basis for diagnosis, and each section contains a very complete printed case history form directed to the development of the histories typical of each system being studied.

The second chapter covers nutrition and vitamin deficiency diseases. It is brief, but complete and well illustrated. The unit standardization of all clinically available vitamins is given. As is true throughout the book, one might differ with particular stunts in treatment that appeal to the author, such as the use of benzedrine in the management of obesity.

The next chapter is on disorders of the digestive tract. Valuable and demonstrative x-ray pictures are reproduced, showing all important organic pathology of the gastrointestinal tract. Anorectal conditions are not neglected. This attention to such common aggravating, minor clinical conditions that make up such an important part of office practice is characteristic of this work, and will go far to make it of great usefulness.

The next main section of the book is on diseases of the blood and blood-forming organs by Dr. Seward E. Miller, Surgeon, U.S. Public Health Service, Chief of the Department of Pathology, U.S. Marine Hospital, Baltimore. This opens with a good modern discussion of various analyses in hemocytometry.

⁴MODERN MANAGEMENT IN CLINICAL MEDICINE. By F. Kenneth Albrecht, M.D. Baltimore: The Williams & Wilkins Co., 1946

¹PÁGINAS DE CIRUGÍA. By Enrique Finochietto. Buenos Aires: La Prensa Medica Argentina, 1945.

²AMBULATORY PROCTOLOGY. By Alfred J. Cantor, M.D. With a foreword by Beaumont S. Cornell, M.D. New York and London: Paul & Hoeber, Inc., 1946.

³SURGICAL TREATMENT OF THE NERVOUS SYSTEM. Edited by Frederic W. Bancroft, A.B., M.D., F.A.C.S. and Cobb Pilcher, M.D., F.A.C.S. Philadelphia, London, Montreal: J. B. Lippincott, 1946.

tients in these large groups were operated upon by the Bassini method. The writer does not know of any statistical follow-up report for a series of cases done by techniques other than the Bassini (as previously defined) furnishing data to which these principles can be applied.

The traditional view of inguinal hernia has it that there are two types, indirect and direct, and that this hard-and-fast compartmentation is maintained throughout the life of the hernia. It notes the increasing frequency of direct hernia with advancing age and muscular relaxation, considers diverticular hernia through Hesselbach's triangle to be rare and conceives the ratio of direct to indirect hernia as being about 1 to 5 in adult males. Those surgeons who, like the writer, believe the results of the Bassini repair to be worse than necessary, although we cannot yet prove that our preferred methods have given better, find much recently recorded evidence that the conception of inguinal hernia just outlined gives a very limited and, in some respects, a false view of the situation. The unusually comprehensive findings of Skinner and Duncan of the United States Public Health Service record that, of 1126 primary inguinal hernias, there were 426 with indirect sacs plus varying degrees of weakness, relaxation, or virtual absence of the posterior wall below the internal ring and 700 direct hernias, including 308 bilocular (i.e., combined) hernias; "few" patients were found to have simple, indirect sacs without enlargement of the aponeuroticofascial margins of the internal ring. Ramos and Burton of the Veterans' Administration, report that the majority of 457 primary inguinal hernias were bilocular. The significance of these findings as to the complexity of the "average" primary hernia in the adult male lies in the fact that their series are the only ones large enough to have statistical significance in which is reported routine exploration for secondary sacs, for thickness and state of tension of the posterior wall, and for the accurate estimation of the size of the internal ring by the introduction of a finger through the opened neck of the sac at the internal ring. This procedure was recommended by Huguot in 1920, by Pitzman in

1921, and more recently by Fallis, Zimmerman, and Harkins, with whose views on the anatomical problems to be met the writer entirely concurs. The series of anatomical papers by Anson and McVay and their later collaborators, beginning in 1937, are unquestionably the most notable anatomical contribution to the subject of hernia to come from the dissecting room in many years. Their pertinent findings in a very large series of dissections are that the inguinal ligament does not receive insertions of the cremasteric portion of the internal oblique or of the transversus aponeurosis and that the inguinal ligament itself is attached only loosely in its midportion to the fascia lata of the thigh. They urged that since the normal insertion of the transversalis fascia is to Cooper's ligament along the superior ramus of the pubis, laxness of the lower portion of the posterior wall should be remedied by suture of the transversalis fascia (and such fibrous elements of the lowest portion of the internal oblique as might be present) not to the inguinal ligament, but to Cooper's ligament. They also point out that the so-called conjoined tendon of the internal oblique aponeurosis and transversalis fascia is a very inconstant structure. The first clinical application of their findings was in the repair of direct hernia but their warning against the use of the inguinal ligament in any part of its course has been extended to the entire field of inguinal hernia repair.

Data on one further, very important technical aspect of the operative treatment of hernia are those furnished by Parsons which present the results of two comparable series of hernias operated on during the same period by the same group, the only difference in technique being that fine silk was used for ligatures and sutures in one series, catgut (size and characteristics unknown) in another. In 458 operations for inguinal hernias of all types in which silk was employed, the recurrence rate was 3.5 per cent; in 244 operations utilizing catgut, the rate of failures was 12.7 per cent. His figures can be tabulated to show that in the 91 cases most likely to failure of the silk series (combined, sliding and recurrent hernias) the recurrence rate was less than 8 per cent in each category, whereas of 49

The actual commercial extracts of liver are listed, with their U.S.P. units.

The chapter on cardiology is extensive and includes a simple and useful discussion of electrocardiography. It is interesting that the use of testosterone propionate in the treatment of angina pectoris is recommended. There is a good chapter on peripheral vascular disease. Buerger's exercises are well illustrated. The treatment of varicose veins by injection is described in detail.

The discussion of diseases of the kidneys quotes completely and verbatim the excellent instructions of Dr. George Thorn for the management of various types of renal insufficiency. As one might expect from the U.S. Public Health Service, the diagnosis and management of venereal diseases has a long, very well illustrated and excellently detailed account. The colored illustrations of skin lesions are excellent.

The chapter on diseases of the respiratory system emphasizes physical findings, but also has an abundance of excellent x-ray reproductions. Pneumothorax treatment of tuberculosis is described in detail.

The chapter on arthritis, as usual, opens with an arthritis case history form. The treatment of rheumatoid arthritis is divided in an interesting manner into those measures of proved value, those which have had optimistic recommendations but of which the value is still undetermined or inconclusive, and those which are of questionable value or are useless.

The section on endocrinology for the general practitioner is of excellent practical value. The discussion of the management of diabetes is simple, very practical, and correct. In this field one might again differ as to a particular procedure, such as the permission to allow excessive thyroid dosage in the treatment of any case of myxedema; for instance, "2 grains three times daily for five days"; or to state "the treatment of myxedema is aimed at elevating the basal metabolic rate." The use of thioracil is discussed, but the dangers of its administration are not sufficiently stressed. More emphasis in this chapter should be placed upon the treatment of the menopause. A useful table of commercial endocrine products with the trade name, the chemical name and the standardization of dosage is given.

The section on allergy is good. It contains a pollen table arranged according to months and states throughout the United States, and directions for desensitization management.

Dr. Miller contributes a useful chapter on toxicology, with a table of a great many poisons with their antidotes.

The infectious diseases are covered with the use of excellent illustrations, and a full discussion of the newest chemotherapeutic agents.

Tropical diseases of post war importance receive for the first time in an American textbook of medicine an adequate, thoroughly illustrated chapter.

There is a long section, as is deserving, on nervous and mental diseases, which opens with the state-

ment: "The idea that the diagnosis of organic disease of the nervous system can be made only by those specializing in neurophysiology, neuroanatomy and neuropathology is too generally accepted by many intelligent practitioners." The use of the well illustrated and complete section which follows should go a long way to change this conception. Mental disorders are approached in an objective manner with an excellent outline of a "neuropsychiatric and psychosomatic case history record." Practical methods of psychiatric examination and modern methods of treatment are then discussed. It is a pleasure to find a practice of medicine including such a useful treatise on the practice of neuropsychiatry.

Again, as one would expect from the U. S. Public Health Service, the diagnosis and treatment of common skin disorders is given full and useful representation.

Chemotherapy and antibiotic therapy are covered in Chapter 18. In harmony with the changing practice of medicine, geriatrics, the care of the aged, receives a chapter of its own. A chapter containing many useful hints for the general practitioner in his important duty of managing the patient at home rather than in the hospital is covered in a chapter labeled "The Care of the Ambulatory Patient."

Finally Dr. Miller adds a short compact chapter on clinical laboratory methods, including that *bête noir* of the general practitioner, the listing of chemical values in milliequivalents per liter rather than in milligrams per 100 cubic centimeter. Not satisfied with such complete coverage, the author adds an appendix covering directions for the performance of many "common procedures," such as thoracentesis, pericardial and abdominal paracentesis, blood typing, and blood transfusion, hydrotherapy, genitourinary treatment, and a list of practical diet menus.

Each of the twenty-one chapters and appendix is followed by a short, but authoritative list of modern references.

In summary one may say that the internist and general practitioner will find this a very helpful and useful work.

PAUL STARR.

The small volume *Motor Disorders in Nervous Diseases* by Ernst Herzl was first prepared as a syllabus to be used together with a collection of teaching motion picture films on the general subject of neurology. Alone, with the many good illustrations furnished, it is actually a descriptive atlas dealing with the testing of motor function and the commoner forms of the pathology of motion.

This book should be a valuable aid to students who are struggling to apply their usual maze of anatomical and physiological facts to the study of actual disease states in patients, since both the illustrations, some of which are good diagrams, and the straightforward and uncomplicated text put the disorders of motor function on a practical, physiological basis. It is pointed out that a large part of any

MOTOR DISORDERS IN NERVOUS DISEASES. By Ernst Herzl, M.D., and Tracy J. Putnam, M.D. New York: King's Crown Press, 1944.

complete neurological examination is concerned with a study of the motor function, and the book proceeds according to a plan which the authors believe to be a logical approach in clinical diagnosis. The common reflexes are shown in photograph form. Such terms as *apraxia*, *dystonia*, and *tic* are illustrated by excellent figures and described in simple, brief, understandable text. Almost half the book is concerned with the motor disorders of the cranial nerves, by no means a disproportionate amount of space for that part of neurological study which is so often confusing to the beginner.

This is not an exhaustive treatise. Its primary purpose is that of use with prepared motion pictures. Nevertheless it is, alone, a book that will be found useful to students and teachers alike. Perhaps the authors will decide to publish a companion text on sensory dysfunction and other special phases of neurological examination.

The book is published by the King's Crown Press, "a division of Columbia University Press organized for the purpose of making certain scholarly material available at minimum cost." The modest price of the book is three dollars. JOHN MARTIN.

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as a sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

HOWARD A. PATTERSON, *Chairman*; FRANK GLENN, *Secretary*

CLINICAL CONGRESS IN NEW YORK POSTPONED BECAUSE OF UNITED NATIONS ASSEMBLY

THE UNITED NATIONS GENERAL ASSEMBLY WHICH WILL BE HELD IN NEW YORK THIS SEPTEMBER HAS MADE IT NECESSARY TO POSTPONE UNTIL 1947 THE LOCAL FEATURES OF THE FOLLOWING PROPOSED PROGRAM IN NEW YORK. THE MATERIAL WAS READY FOR PUBLICATION WHEN IT BECAME NECESSARY TO CANCEL THE 1946 CLINICAL CONGRESS IN NEW YORK AND IT IS THEREFORE BEING PUBLISHED HEREWITH WITHOUT CHANGE. PLANS ARE NOW UNDER CONSIDERATION FOR A MEETING TO BE HELD THIS FALL IN ANOTHER CITY WHERE ADEQUATE ACCOMMODATIONS MIGHT BE AVAILABLE.

NINETY days after arrangements had been completed to hold the thirty-second annual Clinical Congress of the American College of Surgeons in New York from September 9 to 13, plans were announced for the United Nations Assembly in that city during the same month requiring hotel accommodations for around six to eight thousand people. Acting upon authoritative advice, the College at first proceeded with plans for the Congress, and the Committee on Arrangements in co-operation with the local hospitals drew up a most excellent clinical program which is published in succeeding pages. Later developments made it increasingly evident, however, that the Fellows would be put to so much discomfort and inconvenience, if indeed they were able to obtain hotel accommodations at all, that postponement of the Clinical Congress was imperative.

The decision to postpone the Congress was made with especial reluctance because of the fact that no later date this year seems to be available for the meeting in New York. Negotiations are in progress and it is hoped that announcement of a definite date can be made in the very near future. Because of the well advanced stage of the program for both the clinical and scientific sessions, and the superior facilities available in New York for the momentous event which the next Congress will be after so long a period without annual meetings, it is not considered desirable to move to another city unless absolutely necessary. There-

fore, work on the program in New York is proceeding, in accordance with the outline in the following pages.

SIXTH NEW YORK CONGRESS

This will be the sixth time that the Clinical Congress has been held in New York. The first time was in 1912, when the old Waldorf-Astoria was the scene of the third Congress. Dr. George E. Brewer was the Chairman and Dr. Charles H. Peck the Secretary of the 1912 Committee on Arrangements. Dr. Edward Martin of Philadelphia was then President of the Clinical Congress of Surgeons of North America. More than 2,600 physicians registered, and the lack of organization for regulating the attendance at the clinics precipitated the proposal by Dr. Franklin H. Martin at the business meeting on Friday afternoon, November 15, for the creation of the college.

At the same meeting Dr. Allen B. Kanavel presented a resolution which provided that "some system of standardization of hospital equipment and hospital work should be developed, to the end that those institutions having the highest ideals may have proper recognition before the profession, and that those of inferior equipment and standards should be stimulated to raise the quality of their work. . . ." and that "the President of the Congress be authorized to appoint a committee from the profession, delegated to carry the spirit of this resolution into effect, and report at the Clinical Congress in 1913."

Another significant event was the appointment, during an evening session given to the consideration of cancer, held in Brooklyn, of a committee that formed the nucleus of the American Society for the Control of Cancer which was organized following the Congress of Physicians and Surgeons of North America on May 22, 1913.

Thus the plans for formation of the College and for the inauguration of activities in two fields which have always been among its major concerns, hospital betterment and cancer control, were initiated at the 1912 Clinical Congress in New York, 5 years before the Congress was amalgamated with the American College of Surgeons. Later Congresses were held in New York in 1919, 1924, 1931, and 1938.

FIRST POSTWAR CONGRESS

The first postwar Clinical Congress will differ from the meetings for several years prior to the war in that a return will be made to the original custom of holding the *Presidential Meeting* on the opening evening, Monday, and the Convocation on the final evening, Friday, instead of combining them on the first night. There are several good reasons for the change among which is the likelihood of having several hundred surgeons, who have been received into fellowship *in absentia* during the years in which no Convocation was held, added to the number of initiates for the current year who will be present for the initiation ceremonies. Related to this is the need for relieving the pressure for hotel accommodations by distributing the attendance better throughout the week than would be possible if the Convocation were held on the opening night.

COMMITTEE ON ARRANGEMENTS

A representative Committee on Arrangements has been appointed consisting of the following members:

Howard A. Patterson, <i>Chairman</i>	George J. Heuer
Frank Glenn, <i>Secretary</i>	J. William Hinton
Frank E. Adair	Virginius B. Hirst
Albert H. Aldridge	George H. Humphreys
Thomas M. Brennan	Robert H. Kennedy
E. Jefferson Browder	William F. MacFee
George F. Cahill	John H. Mulholland
Henry W. Cave	W. Barclay Parsons
Ralph Colp	Brittain F. Payne
Edward J. Donovan	Otto C. Pickhardt
Merrill N. Foote	Thomas H. Russell
John H. Garlock	Raymond P. Sullivan
Charles A. Gordon	Howard C. Taylor, Jr.
	William Crawford White
	Philip D. Wilson

The Committee has been working diligently for several weeks on plans for the meeting.

CLINICAL PROGRAM

The hospitals and medical schools of greater New York are co-operating in scheduling operative and nonoperative clinics, and group clinical conferences. Visiting surgeons will have ample opportunity to attend well arranged programs of many different kinds in several of the excellent hospitals in the area. General and special demonstrations will be held such as fractures, cancer, maternal morbidity, and end-result studies; clinicopathologic and x-ray conferences; newer diagnostic and therapeutic procedures; preoperative and postoperative supportive treatment; anesthesia; and reconditioning. The newer techniques and surgical procedures may be observed by those who are interested in them.

The medical schools will hold a series of exhibits demonstrating their work which will be on display in their affiliated hospitals. The program of each hospital will be arranged to cover subjects in general surgery, obstetrics and gynecology, fractures, orthopedic surgery, thoracic surgery, neurosurgery, genitourinary surgery, ophthalmology, and otolaryngology.

PRESIDENTIAL MEETING

On Monday evening in the Grand Ballroom of the Waldorf-Astoria, the *Presidential Meeting* will be opened with the impressive procession of the officers, regents, and honorary guests. Welcome to the assembly will be extended by the chairman of the Committee on Arrangements, Dr. Howard A. Patterson. Dr. W. Edward Gallie of Toronto, President of the College, will preside and will deliver the *Presidential Address*. An inaugural ceremony will be held for the incoming officers. Foreign guests will then be introduced.

A new feature to be included in the *Presidential Meeting* this year will be the *first Martin Memorial Lecture*. Dr. Edward D. Churchill of Boston has accepted the invitation to give this lecture. This lectureship was established upon motion of the Board of Regents at its midyear meeting on April 1, as a memorial to both Dr. Franklin H. Martin and Mrs. Martin. Gynecology and Obstetrics was joined by his wife in making the College the beneficiary at their deaths of the Journal, together with its physical plant operated by the Surgical Publishing Company of Chicago, of which they were the owners. Doctor Martin died in 1935 and Mrs. Martin in 1945.

The Martin Memorial Lecture to be given annually during Clinical Congress, and dealing with a scientific subject of the author's choosing, will supplant the former *Annual Oration* in Surgery.

CONVOCACTION

It is planned this year, for various reasons, to depart from the custom of recent years of holding the Presidential Meeting and the Convocation on the same evening. The Convocation is therefore scheduled for Friday evening. An Assembly of Initiates will be held prior to the Convocation on Friday in order to instruct them in the Convocation procedure and other matters.

The Convocation will open with a processional of officers, regents, and governors. The President, Dr. Irvin Abell, will preside and will make the opening remarks, confer the honorary fellowships and present the candidates for fellowship. Following this ceremony, a speaker to be announced later will give the Fellowship Address.

FORUMS ON FUNDAMENTAL SURGICAL PROBLEMS

The Forums on Fundamental Surgical Problems will be conducted on Tuesday, Wednesday, Thursday, and Friday mornings. Included in them will be brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties. No prepared discussions of the reports are planned, but questions and comments will be invited. Especially keen interest is expected in these sessions this year because of the accumulation of the results of 5 years of work since the last Clinical Congress. Dr. Owen H. Wangensteen of Minneapolis, chairman of the committee which is planning the program, is working toward representation of as many as possible of the various university departments of surgery in this presentation of clinical and experimental research work.

The enlistment of the interest of young men who are doing original work, through the forums, is one of the most beneficial results of these sessions which are now considered to be an indispensable feature of every Clinical Congress.

HOSPITAL CONFERENCE

Dr. W. Edward Gallie, President of the College, will address the opening session of the twenty-fifth annual Hospital Standardization Conference on Monday morning at 10 o'clock in the Grand Ballroom, and will preside at the meeting, which will be attended by surgeons and hospital representatives. Following Dr. Gallie's resumé of the Hospital Standardization program of the College, including plans for the future, there will be reports on the progress of the 1946 Hospital Standardization survey, final results of which, including the Approved Lists of hospitals, cancer clinics, and approved hospitals for graduate training in surgery, will be announced at the end of the

year, instead of at the Clinical Congress as was the practice in former years.

The remainder of the Monday morning session will be devoted to talks by medical and hospital authorities on advances in medicine and surgery as they affect the postwar hospital, with particular consideration of their relation to the Hospital Standardization program.

The afternoon conference on Monday will be concentrated upon current problems and the outlook for the future in nursing service. The Tuesday morning conference will have as its main subject personnel management, and the Tuesday afternoon session will be centered around personnel problems in specific fields such as dietary laboratory, medical records, medical social service, x-ray, physical and occupational therapy and other professional and semi-professional services. The discussions will emphasize the importance of scientific management techniques in assuring high quality service from personnel.

The Wednesday morning conference will have as its main theme the importance of assuring high standards of care to the community and all patients through providing in the general hospital facilities for all types of illness. The subject will be discussed from the standpoint of psychiatric, tuberculous, cancer, chronically ill, and convalescent patients. The Wednesday afternoon conference will center mainly around discussion of ways of improving co-operation between general hospitals and special hospitals in the care of all types of special patients.

The Thursday morning conference will revolve around the physical plant of the hospital and the importance of improvement and modernization in raising standards of care of the patient. New mechanical and technical developments will be presented. The afternoon conference will be devoted to the hospital as the health center of the community, with consideration of the effects of this concept upon hospital public relations and upon the progress of preventive medicine and public health.

An evening conference will be held at 7 o'clock on Tuesday. This will be devoted to discussion of the responsibilities of trustees, and members of governing boards will be especially invited to attend and to participate. A conference will be held on Wednesday evening also. This will be a round table conference on responsibilities of hospital administrators, and the preparation which is necessary to enable them to cope successfully with the wide range of administrative problems. The discussion of these problems will interest all hospital personnel.

CLINICAL CONGRESS PROGRAM IN BRIEF

Monday

- 10:00 General Assembly for Surgeons and Hospital Representatives, Grand Ballroom
 1:30-3:00 Panel Discussion, Empire Room
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference, Sert Room
 1:00 Surgical Film Exhibition (General), Grand Ballroom
 3:30-5:00 Panel Discussion, Empire Room
 8:00 Presidential Meeting, Grand Ballroom

Tuesday

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 10:00 Hospital Conference, Sert Room
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Jensen Suite
 9:30-12:00 Forum on Fundamental Surgical Problems, Grand Ballroom
 10:00 Surgical Film Exhibition (General), Empire Room
 11:00 Panel Discussions
 Ophthalmology
 Otorhinolaryngology
 1:30-3:00 Panel Discussion, Grand Ballroom
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference, Sert Room
 2:00 Symposium on Fractures and Other Traumas
 2:00 Surgical Film Exhibition (General), Empire Room
 3:30-5:00 Panel Discussion, Grand Ballroom
 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 7:00 Hospital Conference—Trustees, Sert Room
 8:00 Scientific Session, General Surgery, Grand Ballroom
 8:00 Scientific Session, Ophthalmology, Jensen Suite
 8:00 Scientific Session, Otorhinolaryngology, Le Perroquet Suite

Wednesday

- 8:00 Meeting of Cancer Committee, Carpenter Foyer and Dining Room
 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected Local Hospitals
 9:30 Hospital Conference, Sert Room
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 9:30-12:00 Forum on Fundamental Surgical Problems, Grand Ballroom
 10:00 Surgical Film Exhibition (General)
 State and Provincial Committees:
 Judiciary Committees
 Executive Committees
 Credentials Committees and
 Committees on Applicants } Empire Room
 11:00 Panel Discussions
 Ophthalmology
 Otorhinolaryngology
 12:00 Meeting of Board of Governors, Jensen Suite
 1:30-3:00 Panel Discussion, Grand Ballroom
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Symposium on Cancer, Empire Room
 2:00 Surgical Film Exhibition (General)

- 2:30 Hospital Conference, Sert Room
 3:30-5:00 Panel Discussion, Grand Ballroom
 6:00 Vandyck Reunion Dinner, Le Perroquet Suite
 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 7:30 Hospital Conference, Sert Room
 8:00 Scientific Session, General Surgery, Grand Ballroom
 8:00 Scientific Session (Eye, Ear, Nose and Throat), Empire Room

Thursday

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 9:30 Hospital Conference, Sert Room
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 9:30-12:00 Forum on Fundamental Surgical Problems, Grand Ballroom
 10:00 Surgical Film Exhibition (General), Empire Room
 11:00 Panel Discussions
 Ophthalmology
 Otorhinolaryngology
 1:30 Adjourned Meeting, Governors, Grand Ballroom
 1:45 Annual Meeting, Fellows, Grand Ballroom
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00 Hospital Conference, Sert Room
 3:00 Panel Discussion—Graduate Training in Surgery, Jensen Suite
 3:30-5:00 Panel Discussion, Grand Ballroom
 3:30 Surgical Film Exhibition (General), Empire Room
 3:30 National and Regional Fracture Committees, Le Perroquet Suite
 4:00 Committee on the Library, Room 4-J
 7:00 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 8:00 Scientific Session, General Surgery, Grand Ballroom
 8:00 Scientific Session, Ophthalmology, Empire Room
 8:00 Scientific Session, Otorhinolaryngology, Sert Room

Friday

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 9:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat), Empire Room
 9:30-12:00 Forum on Fundamental Surgical Problems, Grand Ballroom
 10:00 Surgical Film Exhibition (General), Empire Room
 1:30-3:00 Panel Discussion, Surgery of the Stomach
 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals
 2:00-4:00 Panel Discussions
 Obstetrics, Sert Room
 Plastic Surgery, 4-U Blue Room
 Neurological Surgery, Assembly Room M-N
 Thoracic Surgery, Jensen Suite
 Urology, Le Perroquet Suite
 Orthopedic Surgery, Carpenter Foyer and Dining Room
 2:00 Surgical Film Exhibition (General), Empire Room
 3:30-5:00 Panel Discussion, Surgery of the Vascular System
 8:00 Convocation, Grand Ballroom

ANNUAL MEETING OF FELLOWS

The annual meeting of the Governors and Fellows will be held on Thursday afternoon at 1:45. There will be election of officers and governors. The annual meeting affords the Fellows of the College an opportunity to hear reports of officials on the work of the organization, and to learn how it has not only raised the professional and ethical standards of surgery, but has also promoted good hospitalization and general improvement in the practice of medicine in the United States and Canada. Each Fellow has a personal part in this work and may extend the influence of the College materially in his local community. Hospital Standardization alone offers him unlimited opportunity to provide better medical care for his patients in the hospital in which he works through continuous progress in applying the principles of the Minimum Standard which insure the best care of the patient.

Every Fellow will want to attend this important meeting, at which reports will be presented on financial affairs; Hospital Standardization; Graduate Training in Surgery; Medical Motion Pictures; Public Relations; Library and Literary Research; the work of the state and provincial credentials committees, committees on applicants, and the Committee on History Reviews; Sectional Meetings, 1946; and the Department of Clinical Research, including cancer clinics, medical service in industry, the Committee on Cancer, and the Committee on Fractures and other Traumas. Dr. Abell will report on administration of the College, staff changes, and retirements, and Dr. Arthur W. Allen, Vice-Chairman of the Board of Regents will discuss "Fellowships, Obligations and Opportunities."

STATE AND PROVINCIAL EXECUTIVE, CREDENTIALS
AND JUDICIARY COMMITTEES

On Wednesday morning from 9:00 to 12:00 o'clock the State and Provincial Executive, Credentials, and Judiciary committees will meet to discuss their respective activities.

MEDICAL MOTION PICTURES

The latest available films showing surgical procedures and related subjects will be shown in the medical motion picture exhibits which will be held daily. These are a much appreciated feature of the Clinical Congress. Despite the decrease in production of such films during the war period, a surprising number of new pictures on varied subjects are being received by the American College of Surgeons for review.

The schedule will be so arranged as not to conflict with either the clinical program at the hospitals or the scientific sessions. Both sound and silent, standard and color films will be shown, all of which have been approved by the Committee on Medical Motion Pictures.

TECHNICAL AND SCIENTIFIC EXHIBITION

The technical exhibit, together with the registration and clinic ticket bureaux, will be located in the Basildon Room, Jade Room, and Astor Gallery, all on the third floor of the hotel. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, pharmaceuticals, and publishers of medical books will be represented in the exhibition. The technical exhibits will demonstrate many of the newer features learned from our experience in the war.

EVENING SCIENTIFIC SESSIONS

GENERAL SURGERY

Tuesday

Care of the Patient before and after Operation

Fluid and Electrolyte Balance. CARL MOYER, Eloise, Michigan.

Nutritional Preparation of the Substandard Risk Patient. RICHARD L. VARCO, Minneapolis.

Use of Blood and Blood Substitutes. JOHN D. STEWART, Buffalo.

Blood Transfusion Problems, with Special Reference to the Rh Factor. ALEXANDER S. WIENER, Brooklyn.

Safe Conduct of the Patient Through Operation. OWEN H. WANGENSTEEN, Minneapolis.

Wednesday

Venous Thrombosis and Prevention of Pulmonary Embolism

Interruption of Deep Veins. ARTHUR W. ALLEN, Boston.

Sympathetic Nerve Block. ALTON OCHSNER, New Orleans.

Anticoagulants. D. W. GORDON MURRAY, Toronto.

Fracture Oration

Modern Methods in the Treatment of Fractures. EDWIN W. RYERSON, Chicago.

Thursday

Antibiotic and Chemotherapeutic Agents in Surgery

Pathologic Physiology of Surgical Infections. JOHN S. LOCKWOOD, New Haven.

Penicillin—its Use in Surgery and Influence on Earlier Types of Chemotherapy. WILLIAM A. ALTMAYER, Cincinnati.

Streptomycin. HORTON C. HINSHAW, Rochester.

Correlation of the Use of Antibiotic and Chemotherapeutic Agents with General Principles of Surgery. CHAMP LYONS, New Orleans.

OPHTHALMOLOGY

Tuesday

Orbital Reconstruction Including Prosthesis

Acrylic Prosthesis.

Basket Implant. NORMAN L. CUTLER, Wilmington.

Orbital Measurements.

Reconstruction of Upper Lid and Orbital Floor Defects. Major ARTHUR E. SHERMAN, Springfield, Missouri.

Thursday

Surgical Applied Anatomy in Eye Surgery. MEYER WIENER, Coronado.

Treatment of Glaucoma with Di-Isopropyl Fluorophosphate. PHILLIP ROBB McDONALD, Philadelphia.

Visual Disturbances Associated with Head Injuries.

OTORHINOLARYNGOLOGY

Tuesday

Treatment of Deafness

The Suppurating Ear.

The Fenestration Operation. GEORGE E. SHAMBAUGH, JR., Chicago.

Use of Radium for Conductive Deafness. JOHN E. BORDLEY, Baltimore.

Thursday

Surgery of the Nasal Accessory Sinuses

Indications for Surgery in the Light of the Use of Antibiotics.

Intranasal Surgery. JOHN J. SUEA, Memphis.

External Operations.

SYMPOSIUM ON PLASTIC SURGERY OF THE HEAD AND NECK

Wednesday 8 p.m.

Cancellous Bone Grafts to the Jaw.

Repair of Nasal Defects with Free Composite Grafts of Skin and Cartilage from the Ear. JAMES B. BROWN, St. Louis.

Studies in the Anatomy and the Repair of Cleft Palate.

Preservation of Function Following Resections of Jaw Tumors.

PANEL DISCUSSIONS

GENERAL SURGERY

Monday, 1:30-3:00 p.m.

Rehabilitation of the Surgical Patient and Early Ambulation. Leader, HOWARD RUSK, New York.

Monday, 3:30-5:00 p.m.

The Treatment of Cancer of the Large Bowel. Leader, FREDERICK A. COLLIER, Ann Arbor.

Tuesday, 1:30-3:00 p.m.

Thiouracil in Thyroid Disease. Leader, FRANK LAHEY, Boston.

Tuesday, 3:30-5:00 p.m.

Recent Trends in the Management of Carcinoma of the Cervix. Leader, JOE VINCENT MEIGS, Boston.

Wednesday, 1:30-3:00 p.m.

Anesthesia. Leader, HENRY K. BEECHER, Boston.

Wednesday, 3:30-5:00 p.m.

Protein Metabolism in the Surgical Patient. Leader, ROBERT ELMAN, St. Louis.

Thursday, 3:30-5:00 p.m.

Spinal Cord Injuries. Leader, HOWARD C. NAFFZIGER, San Francisco.

Friday, 1:30-3:00 p.m.

Surgery of the Stomach. Leader, ROSCOE R. GRAHAM, Toronto.

Friday, 3:30-5:00 p.m.

Surgery of the Vascular System. Leader, DANIEL C. ELKIN, Atlanta, Georgia.

SURGICAL SPECIALTIES

Friday 2:00-5:00

Orthopedic Surgery Panel. (Subject to be announced.) Leader, CARL E. BADGLEY, Ann Arbor.

Urology Panel. (Subject to be announced.) Leader, HERMAN L. KRETSCHMER, Chicago.

Plastic Surgery Panel. (Subject to be announced.) Leader, ROBERT H. IVY, Philadelphia.

Neurological Surgery Panel. (Subject to be announced.) Leader, FRANCIS C. GRANT, Philadelphia.

Obstetrics Panel. (Subject to be announced.) Leader, FREDERICK C. IRVING, Boston.

Thoracic Surgery Panel. (Subject to be announced.) Leader, RICHARD H. SWEET, Boston.

OPHTHALMOLOGY

Panel discussions in the field of Ophthalmology are planned for Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock, on the following subjects: Retinal Detachment; Glaucoma; Keratoplasty.

OTORHINOLARYNGOLOGY

Panel discussions on subjects in the field of Otorhinolaryngology are planned for Tuesday, Wednesday and Thursday mornings at 11:00 o'clock on the following subjects, respectively: The Treatment of Ménière's Syndrome; Osteomyelitis of the Skull; Rehabilitation of War Deafness.

SYMPOSIUM ON FRACTURES AND OTHER TRAUMAS

At 2:00 o'clock on Tuesday afternoon there will be held a symposium on Fractures and Other Traumas under the direction of Robert H. Kennedy of New York. This symposium will be devoted to a number of brief presentations by specialists in various fields concerning new or improved methods adopted during the war which are applicable to injury in civilian surgery. The aim is to give a rapid survey of worthwhile gains made during the war which may prove of lasting value in the field of trauma.

Among the fifteen or twenty short papers which are planned are the following:

Bone Grafts. GEORGE K. CARPENTER, Nashville.
Spinal Cord Injuries. DAVID H. POER, Atlanta.

Injuries to the Rectum. EDMUND J. CROCE, Worcester.

Transportation of Fractures. WILLIAM J. STEWART, Columbia.

Replacement of Skin Defects. JAMES B. BROWY, St. Louis.

Fractures of the Carpal Scaphoid. MATTHEW CLEVELAND, New York.

Amputations. RUFUS H. ALDREDGE, New Orleans.

Training of Amputees. HENRY H. KESSLER, Newark.

Rehabilitation. Col. A. WILLIAM REGGIO, Washington.

Compound Fractures Treated with Penicillin and Delayed Primary Closure. OSCAR P. HAMPTON, Jr., St. Louis.

SYMPOSIUM ON CANCER

A symposium on cancer is planned for Wednesday afternoon. The Cancer Committee of the College has done outstanding work in furthering the development of cancer clinics in hospitals and providing for the registration of cured cases of malignant disease in the cancer archives. The chairman of this com-

mittee will give a brief review of these activities of the College in opening the symposium.

Other subjects of practical interest are under consideration for inclusion in the program, which is being planned to interest surgeons, pathologists, and radiologists.

similar cases closed with catgut, the rate of failure was above 20 per cent for each group. Although there are objections to accepting Parson's figures as being truly indicative of the ultimate rates of failure (all were done by a modified Bassini technique), yet the superior performance of silk over catgut can be accepted without reservation in one respect and with considerable reservation in another. That the recurrence rate followed the rate of wound infection (with approximately a ratio of 1 to 3 in favor of silk) throughout all his cases is clear. But since the length of time in which confinement to bed after operation was enforced is not alluded to, the influence of this factor in wound healing of his cases is not known. It is notoriously true that wounds sutured with catgut, however fine, heal more slowly than when silk is employed and those of us who used fine catgut extensively in the past were quite aware that in wounds whose anatomic and physiologic characteristics made them liable to separation under stress, it was necessary to enforce recumbency for a longer period before a firm scar was obtained than would have been the case with silk. This, in the view of the surgeon familiar with the processes of wound healing, elementary in the postoperative management of the patient whose wound is sutured only with catgut. No data on the occurrence of herniation through any operative incision having the characteristics described are complete without a clear statement of the duration of strict confinement to bed in a position of semirecumbency. This realization seems to be missing from much surgical thought today and will require emphasis in the current trend to early ambulation. Shelley (16, 17, 18) found that in 1110 repairs of primary indirect inguinal hernia without postoperative complications, in whom the postoperative hospital stay (not confinement to bed) was for the 11 to 15 days, customarily in that institution, recurrences occurred in 7 per cent of the patients. A group of 336 patients with similar operations were confined to the hospital for 16 days or more because it was feared that they might develop complications, yet in them there were only 4.5 per cent of failures! Only catgut was used in either series.

Let us enumerate and comment on those steps which the writer regards as being essential to the performance of a radical hernioplasty with the smallest risk of failure. It is to be understood that the posterior wall of the inguinal canal is not merely the portion of Hesselbach's triangle between the inferior margin of the internal ring and the pubis, but also extends upward along the medial and lateral margins of the internal ring to its uppermost aspect; in patients with indirect hernia, the ring is invariably enlarged beyond the accepted normal dimensions, once its aponeuroticofascial margins have been demonstrated. This has been the observation of the writer in over 160 personally operated upon inguinal hernias on Naval personnel, of whom almost all had an indirect factor so far as the sac is concerned.

There are three major objectives of operation: (1) exploration of the components of the hernia (the sac, its contents and the abdominal wall of the inguinal region); (2) excision of the sac, whatever its characteristics, and closure of the peritoneum; (3) such plastic revision of the abdominal wall as may be indicated (complete or limited). Performance of the following steps will facilitate the accomplishment of these objectives.

1. Mobilization of the cremaster from its uppermost insertions into the transversus abdominis at the lateral margin of the internal ring and from its origins in the internal oblique muscle about the superior and medial margins of the external ring. Excision of these highest fibers of the cremaster exposes the medial and lateral margins of the internal ring, defines the free margin of the internal oblique muscle which is then retracted superiorly to expose the entire cord bundle and indirect sac in their passage through the internal ring. Excision of this portion of the cremaster also reduces the size of the cord bundle in the portion of its length which is to be brought out of the internal ring in closure and assures fascia-to-fascia approximation of the margins of the transversus aponeurosis. An intact cremaster is the greatest obstacle to identification of the transversus aponeurosis (or to realization of its existence as a readily accessible structure) known to the writer.

PRELIMINARY CLINICAL PROGRAM—NEW YORK

BELLEVUE HOSPITAL

Monday

Anesthesia—2.

E. A. ROVENSTINE and staff. Dry clinic: Management of anesthesia for intrapleural surgery. Nerve block demonstrations: glosso-pharyngeal block for diagnosis; sympathetic block for phantom pain; paravertebral block for fracture of ribs; suprascapular block for shoulder pain; discussion of drugs and methods. Exhibit: A male moulage is utilized to demonstrate the landmarks for various nerve blocking procedures.

Neurosurgery—2.

JOSEPH KING, WILFRED WINGEBACH, LAWRENCE POOL, HERBERT REIKERT. Operative clinics.

Ophthalmology (time to be announced).

DANIEL B. KIRBY. Cataract surgery; ptosis and strabismus surgery.

ARNO E. TOWN. Cornea.

JAMES HOULAHAN. Glaucoma.

LOREN P. GUY. Lacrimal passages.

Radiation therapy—2.

IRA I. KAPLAN, RIEVA ROSH, SIDNEY RUBENFELD. Dry clinic: Head and neck cases.

Urology—2.

ROBERT HOTCHKISS and HOWARD JECK; JOHN W. DRAPER and JOSEPH REIKERT; GUSTAV HUMPHRIES and GEORGE SLAUGHTER; DEAN MAKOWSKI.

Tuesday

General surgery—Operative clinics—8.

JOHN H. MULHOLLAND, THOMAS J. GALVIN, VICTOR CARABBA, SAMUEL STANDARD, IRWIN E. SIRIS, JOHN A. LAWLER, H. M. WERTHEIM.

Dry clinic—10.

SAMUEL STANDARD. Results of anterior resection for carcinoma of rectum.

JOHN A. LAWLER and ELAINE P. RALL. Postoperative thyroid results.

HENRY DOUBILET. Pancreatic enzymes.

CO TUI. Protein metabolism.

WALLACE B. MURPHY. Management of static ulcers.

VICTOR CARABBA. Results of repair of body defects by free fascial grafts.

WALTER B. CRANDELL. Vagus nerve resection for ulcer of stomach and duodenum.

JOHN HALL. Acute arteritis of the appendix.

SIGMUND WILENS. Tissue reaction to talc.

Fractures and other traumas—round table discussion—2.

Fracture dislocation of the surgical neck of the humerus. Fractures of the neck of the humerus. Fracture dislocations of the elbow. Plateau fracture of tibial condyles. Fracture dislocations of the ankle. CARNES WEEKS, HERBERT J. REIKERT, IRWIN E. SIRIS, KENNETH M. LEWIS.

Obstetrics and gynecology: Operative clinic—8; Dry clinic—10.

MORTIMER D. SPEISER. Management of unengaged vertex in multiparae at full cervical dilatation.

IRVING PERLMUTTER. Indications for therapeutic abortion at Bellevue Hospital, 1935-1945.

HERBERT B. GUYER. Precinical cancer of the cervix—case report of 7 year history.

EQUINN W. MUNNELL. Management of the delivery of the second of twins.

LOUISE M. DANTUANO. Staphylococcus bacteremia—three cases.

Physical medicine—2.

GEORGE G. DEEVER. Demonstration and motion picture: Rehabilitation of spinal cord injuries. Discussion: Evaluation of extent of disability; methods of treatment for ambulation and self-care.

Radiation therapy—2.

IRA I. KAPLAN, RIEVA ROSH, SIDNEY RUBENFELD. Dry clinic: Breast and miscellaneous cases.

Wednesday

General surgery: Operative clinics—8. Dry clinic—10.

FRANK B. BERRY and associates

PHILIP C. POTTER, CARNES WEEKS, ROBERT WYLLIE,

DWIGHT B. FISHWICK, JAMES BAGG, WALLACE W.

SHERIDAN, WALTER W. FISCHER, ROBERT B. HYATT,

WILLIAM HEROV, AARON HIMMELSTEIN.

Chest service: Operative clinic—8. Dry clinic—2.

FRANK B. BERRY and associates

HERBERT C. MAIER, ADRIAN LAMBERT, JR., LAURENCE

MISCALL, CHARLES W. LESTER, WALTER B. CRAN-

DELL.

Thursday

General surgery: Operative clinics—8. Dry clinic—10.

ARTHUR S. McQUILLAN. Thyroid disease.

J. WILLIAM HINTON. Stomach.

LESTER BREIDENBACH. Colon.

EDWARD V. DENNEN. Gall bladder.

L. BREIDENBACH. End-results: stricture of rectum from lymphogranuloma venereum.

Children's surgery: Operative clinics—2. Dry clinic—3:30.

PHILIP ALLEN. Hernia.

CHARLES LESTER. Chest Surgery.

Dental surgery: Dry clinic—3:30.

LEO WINTER.

Fractures and other traumas—8.

KENNETH M. LEWIS. Fracture of femur (neck).

Orthopedic surgery: Operative clinics—2. Dry clinic—3:30.

JOHN McCauley and ARTHUR KRIDA.

Friday

General surgery: Operative clinics—8:30.

GUILFORD S. DUDLEY. Abdominoperineal resection for carcinoma of the rectosigmoid.

RUSSELL H. PATTERSON. Vascular operative clinic.

CRANSTON HOLMAN. Subtotal gastrectomy for peptic ulcer.

ERNEST W. LAMPE. Thoracolumbar sympathectomy.

Dry clinic—10:30.

LAURENCE MISCALL. Unusual cardiopulmonary wounds. Report on the diagnosis and treatment.

DAVID LYALL and JOHN LUOMANEN. Richter's hernia—a report on 17 cases.

JOHN LUOMANEN and PRUDEN. Internal fixation of fractures of the neck of the femur.

RUSSELL H. PATTERSON. The rôle of venogram in vascular surgery with a report of some unusual cases.

SAMUEL W. MOORE. Peptic ulcer perforation—a report on a series.

HERBERT REIKERT. Gastrojejuno-colic fistula—a report of 7 cases.

Otorhinolaryngology: Operative clinic—2. Dry clinic—3:30.

SURGERY, GYNECOLOGY AND OBSTETRICS

JOSEPH D. KELLY and staff. Laryngeal surgery. Presentation of cases.

Röntgenology Exhibition
Roentgen illustration of inflammatory and neoplastic lesions. LEWIS J. FRIEDMAN. Tuesday through Friday—2-4 P.M.

BETH ISRAEL HOSPITAL

Tuesday
ARTHUR J. BARSKY—9. Plastic surgery: Operations.
SEYMOUR F. WILHELM and staff—2. Urology: Operations.
Wednesday
SIDNEY W. GROSSE and staff—9. Neurosurgery: Operations.
HENRY C. FALK and staff—9. Gynecology. Operative and dry clinic.
PERCY KLINGENSTEIN and staff—2. Surgery: Operative and dry clinic.
EDWIN G. LANGROCK and SAMUEL J. SCADRON and staff: 2. Operative obstetrics.

Thursday
Gynecology: Operative and dry clinic—9.
ARTHUR S. W. TOUROFF—2. Chest surgery.

Friday
IRVIN BALENSWEIG and staff—9. Orthopedics: Operative and dry clinic.
SOLOMON G. HERSHEY and staff—9. Anesthesiology.
EDWIN G. LANGROCK and SAMUEL J. SCADRON—2. Tumor clinic; obstetrical clinic.
Pantopaque myelography in diagnosis of herniated intervertebral disc.

FLOWER AND FIFTH AVENUE HOSPITALS

Monday
Neurosurgery—3.
ISADORE MAX TARLOV. Technique of nerve suturing and grafting by plasma clot.
THOMAS IRVING HOEN. End-results.

Tuesday
Breast Surgery—9.
HERBERT CLIFTON CHASE. Carcinoma of the breast; demonstrations and end-results.
Tumor clinic—11.
GEORGE THOMAS PACK, GEORGE HIGGINS and FRANK JAMES BORRELLI.
Thoracic surgery—2.
SAMUEL ALCOFF THOMPSON and staff. The results of surgical treatment of aniginal disease.
Obstetrics—2.
HORACE ERNEST AYERS, L. S. LOUZEUX and staff. Demonstration on the Ayers mannequin; moving picture with sound and color.
Orthopedics and fractures—2.
MILTON JOHN WILSON, ALAN CANTWELL and staff. Fracture treatment with motion pictures and end-results demonstrations.

Wednesday
JEROME GEORGE KAUFMAN, C. HENRY MERSHMEIER, and THOMAS H. MCGAVACK—9. Surgery of the thyroid and the use of Thyreac preparations.
LANGE and JOHN S. O. HERRLIS, Jr.—11. The test of viability of the bowel by the fluorescein method.
JOHN FOLENER FORD and DAVID MCCULLAGH MAYER—3. Dry clinic showing the methods employed in reconstruction of the external ear.

Ophthalmology—2.
JOHN MILTON McLEAN. Demonstration of the Ba-roquer phaco-erysis operation for cataract.
CHARLES AARON TURTZ and CARL CONRAD SALTZ. Squint operation.

Thursday
JOSEPH H. FORBES, JOHN CLIFFORD HAYNER and ALF GRAHAM—9. Hernia; a new operation for hernia end-results; discussion of wound healing.
—10:30. Femoral vein ligation for phlebotrombosis, femoral vein ligation for chronic thrombophlebitis, and embolectomy—indications and end-results.
Plastic surgery—2.
CLARENCE RALPH STRAATMHA. Plastic surgery in otolaryngology—2.
J. A. W. HETRICK and ARTHUR J. HERSIG. End results of tonsillectomy.

Friday
JOHN S. HERRLIN—9. Accidents to the common duct. Indications for common duct surgery and methods for reconstruction.
FRANCIS DAVIS SPEER—10. Water balance.
JOHN S. HERRLIN—10. Surgical aspects of water balance.
CHARLES A. HALBERSTADT and MICHAEL GEORGE METZRO—11. A new amino acid preparation; its clinical use.

GOLDWATER MEMORIAL HOSPITAL

THE THIRD SURGICAL (N.Y.U.) DIVISION
Monday through Wednesday (time to be announced)
WILLIAM H. BARBER, HAROLD B. KEVES and staff. C. ulcerative colitis.
WILLIAM H. WALKER and staff. Non union and contractures.
GEORGE W. SLAUGHTER and staff. Genitourinary problems in the aged.
MARGARET STANLEY-BROWN, NED SANAYEVSON and staff. Peripheral vascular disease.

HARLEM HOSPITAL

Monday
Burns and plastic surgery symposium—2.
JOSEPH A. TAMERIN. Resurfacing of extensive burn. Clinical cases and lantern slides.
ARTHUR L. GARNES. The problem of shock in burn.
GASTRIE and BILARY surgery symposium—3:15.
AUBRE D. MAYNARD. Problems in biliary surgery.
JOHN P. BRUCKNER. Gastric surgery.
FRANCIS X. TIMONEY. Use of sulfonamides in peptic ulcer.

Tuesday
Trauma symposium—9.
RALPH H. YOUNG. Ward rounds—male building, followed by discussion of basic principles of traumatic surgery and nontraumatic surgery.
DAVID H. SMITH. Head injuries: Presentation of cases stab wounds and functional tests.
AARON PRIGOT. Injuries of liver, traumatic rupture, stab wounds and functional tests.
ROBERT S. WILKINSON. Stab and gunshot wounds of abdomen.
MYRA A. LOGAN. Stab wounds of the heart.
—Roentgenology in surgery—2.
WILLIAM SNOW. Duodenal loop triad.
LEON GENZBURG. Intestinal obstruction and regional ileitis.

Genitourinary conference—3:30.

NORMAN F. LASKEY and staff. Kidney and bladder trauma with presentation of cases; urethral stricture; renal calculi.

Wednesday

FRANCIS X. TIMONEY. Ward rounds, Woman's building. Traumatic and nontraumatic cases.

LOUIS T. WRIGHT and JOSEPH LEVY. The problem of rectal stricture; presentation of cases.

BENJAMIN N. BERG. Pancreatic disease.

Gynecological symposium—2.

HENRY C. FALK and staff. Operative clinic in gynecological surgery; dry clinic: pelvic inflammatory disease.

Thursday

Fracture and orthopedic symposium—9.

ARTHUR C. LOGAN, WILLIAM A. FREEMAN, ANTHONY T. PRIVITERA. Fractures of the femur, with demonstrations and correlated operations.

JOSEPH G. WISNER and staff. Slipped epiphysis with clinical demonstration.

SAMUEL SHENKMAN. Treatment of cervical spine with fracture.

LOUIS T. WRIGHT. Traumatic ward rounds.

Obstetrical symposium—2.

FREDERICK A. KASSEBOHN. Obstetrical emergencies and their treatment.

ABRAHAM C. POSNER. Recent advances in the toxemia of pregnancies.

JULIUS KURZROCK. The technique of Barton's forceps.

M. SCHREIBER. Analgesia in obstetrics.

NORMAN P. PLESSETTE. Tumors complicating pregnancy and labor.

WILLIAM SNOW. Soft tissue diagnosis by x-ray in obstetrics.

Friday

Thyroid disease—9.

ALEXANDER ALTSCHUL. Medical aspects of thyroid disease.

JESSE J. GREENE. Surgical aspects of thyroid disease.

Symposium on chest diseases—9:30.

JAMES C. WHITAKER. Injuries of the chest.

FARROW R. ALLEN. Thoracoplasty.

COSTABILE DI LORENZO. Surgical diseases of the chest.

DOMINICK F. ZETENA—10:10. Pediatric surgery.

ANGELO A. ZINGARO—11. Diverticulitis.

JAMES L. WILSON and ROBERT L. NACH—11:30. Amputation and the use of refrigeration anesthesia.

ANTHONY T. PRIVITERA—9. Traumatic ward rounds.

LOUIS T. WRIGHT—2. Mortality conference.

SOLOMON WEINTRAUB—2. Surgical pathology demonstrations.

The staff—2. Unusual cases.

HARLEM EYE AND EAR HOSPITAL

Wednesday

Otorhinolaryngology—1. Operations—Tonsillectomies with Meding tonsil enucleator.

Ophthalmology—2. Cataract extraction—Caldwell Luc.

Otorhinolaryngology—3. Demonstration of ear, nose and throat cases.

HOSPITAL FOR JOINT DISEASES

Monday

LEO MAYER and staff—8. Operative clinic. Tendon transplantation on the foot for traumatic division of flexor tendons; tendon transplantation in the hand for traumatic division of flexor tendons; fusion of the hip by new approach.

SAMUEL KLEINBERG and staff—2. Dry clinic. Demonstration of cases illustrating results of tendon transplants in the hand and foot and fusion operations on the hip: epiphysiolithesis—results of drilling in early cases; chronic osteomyelitis—results of operation combined with use of penicillin; flat feet—indications for and results of Miller operation; club feet—manipulative and operative treatment; Perthes' disease.

Tuesday

SAMUEL S. KLEINBERG and staff—8. Operative clinic. Spine fusion for chronic low back pain; herniation of intervertebral disc (A. KAPLAN); arthrotomy for internal derangement of the knee; epiphysiolithesis—drilling; contracted toes—plastic operation; congenital dislocation of the hip—open reduction.

Wednesday

ISADORE I. ZADEK—8. Orthopedic cases—operations; treatment of ununited fracture of hip. Obturator nerve avulsion for painful hip.

HARRY GOLDMAN—8. Operative clinic: Hemorrhoids; fistula-in-ano; benign adenoma of rectum.

PAUL WILLIAM ASCHNER—1:30. Operations on kidney and bladder.

HARRY DAVID SONNENSCHNEIN—2. Dry clinic orthopedic cases.

Thursday

HARRY DAVID SONNENSCHNEIN and staff—8. Operations: arthrotomy of knee; lumbosacral fusion; transcervical plastic for radial nerve lesion.

HAROLD BERTRAM DAVIDSON and staff—1:30. Total hysterectomy for fibroids.

Friday

ABRAHAM JACOB BELLER and staff—8. Operations for carcinoma of stomach and colon.

HOSPITAL FOR SPECIAL SURGERY

Tuesday

PHILIP DUNCAN WILSON and staff—9. Children's orthopedic problems.

LEWIS CLARKE WAGNER—9. Severe spondylolisthesis—case presentation.

General surgical operations—8:30.

Wednesday

Children's orthopedic surgery—8:30.

CARL GOODWIN BURDICK and staff—9; 2. Hernia and special surgical problems.

Plastic surgery—9; 2.

YOLANDE E. H. HUBER and JOHN MARQUIS CONVERSE. Presentation of cases; motion pictures; plastic surgical operations.

Thursday

Surgery of bones and joints—9; 2.

PHILIP DUNCAN WILSON and staff. Adult orthopedic problems.

LEWIS CLARKE WAGNER. Wedge osteotomy of neck of femur for badly displaced upper femoral epiphysis.

L. RAMSAY STRAUB. Spine fusion with plate fixation.

PHILIP DUNCAN WILSON. Trochanteric cup arthroplasty.

THEODORE C. THOMPSON; LEWIS CLARKE WAGNER.

Restoration of active knee motion.

ROBERT LEE PATTERSON, JR. Conservative treatment of fractures of the tibial plateau.

WILLIAM MORRIS COOPER. Aseptic necrosis of the head of the femur in adults.

PETER RIZZO. Bone graft with metallic fixation.

JOHN J. FLANAGAN. Massive tibial bone grafts.

SURGERY, GYNECOLOGY AND OBSTETRICS

Friday
Surgery of bones and joints—8:30.
RICHARD FRENBERG and staff. Arthritic problems.
Adult orthopedic surgery.
JOHN ROBERT COBB and staff—2. Scoliosis—idiopathic and paralytic.

LENOX HILL HOSPITAL

Monday
Obstetrics and gynecology—2.
ROBERT MCCREADY and MORTIMER ROGERS. Total hysterectomy by combined vaginal and abdominal routes.
Operative treatment of prolapse.
NATHAN BRISTOL VAN ETTEN. Total abdominal hysterectomy.
EDWARD P. KILROE. Vaginal hysterectomy.
CUNNINGHAM. Manchester-Fothergill operation.
BOYNTON. LeFort operation.
CARL GOLDMARK. Obstetrical analgesia—demerol versus barbiturates.

Tuesday
Surgery—9.
JOHN C. GERSTER, FRANCIS M. DONOHUE, HERBERT W. MEYER, ERIC FRICKE. Choice of operative procedures in lesions of colon and rectum.
Thoracic surgery—2.
C. EGGERS. Thoracic cases.
HERBERT CAILLE MAIER. Results of lobectomy and pneumonectomy in bronchiectasis, cystic disease of the lung and pulmonary abscess.

Wednesday
Fischer. Surgical treatment of adenoma of bronchus.
Surgery—9.
OTTO CARL PICKHARDT. Treatment of hiatus hernia in older people by phrenicoplasty.
GEORGE ERNEST MUELLER. Acute pancreatitis.
HUBER. Symptomatology, diagnosis.
BLAKE FERGUSON DONALDSON. Operative procedure.
LEROY ALVIN WIRTILIN. End-results.
Gentle surgery—2.
WILLIAM ROBERT DELELL. Unusual calculi of urinary tract.

MAXIMILIAN MARK NEMSER. Polycystic kidney disease.
SLAUGHTER. Treatment of rupture of urinary bladder.
Ophthalmology—2.
CHRISTIAN FREDERICK REID. Transplantation of mucous membrane for eye burns and keratitis.
CHRISTIAN F. KETELS, JOHN HENRY BORN, RUDOLPH AEBLI, BERNARD FREED, SAUER, ERNEST LUDWIG METZGER. Cataract surgery. Dry clinic postoperative: cases of retinal detachment.
Ophthalmology clinic—2.
RUDOLPH AEBLI and staff. Cataract operations; clinic on retinal detachments (demonstration of cases).

Thursday
Diagnostic-Bronchoscopic clinic—9.
ARTHUR JOSEPH CRACOVANER, HIRSCH. Bronchoscopy—indications and demonstration.
HENRY PAUL SCHUCH. Tuberculosis of larynx; abscess of larynx.
ERNEST ALFRED WEYMULLER. Acro-otitis and sinusitis—irradiation therapy.
J. E. JOHNSTONE KING. Neurosurgery.
Hematology and vascular surgery symposium—2.
CARL REICH. Heparin and dicumaryl.
RICHARD WILLIAM KESSLER. Anatomy and operative procedures.
ECHLIN. Neurosurgery procedures.

McWILLIAMS. Venography.
GEIGER. Rb factor and blood bank demonstration.
Friday
Surgery of the bones and joints—9.
WALTER ISAAC GALLAND. Osteotomy for osteoarthritis of hip.
WALKER ELY SWIFT. Fracture—dislocation of ankle.
ALFRED FRANZ WIESENTHAL. Hallux valgus—management and end-results.
HENRY H. JORDAN. Roger Anderson pinning of fractures—end-results; hospital brace shop demonstration.
MADGE C. L. MCGUINNESS. Discussion of general physical therapy procedures.
FRED SQUIER DUNN. Cleft palate.
GUSTAVE AUFRICHT. Mammoplasty.

LYING-IN HOSPITAL

Monday
HENRICUS JOHANNES STANDER presiding—2. Presentation and discussion of interesting patients.

Tuesday
BYRON HEAZELTON GOFF and JAMES AITKEN HARRAI. Operative clinic: Vaginal plastic operations; obstetrical operations.
CHARLES MORDECAI McLANE. X-ray pelvimetry.
JACOB THEODORE SHERMAN. The obstetrical pelvis from a clinical aspect.
FREDERICK WALL FINN. Evaluation of myomectomies.
JOHN T. COLE. Maternal obstetrical paralysis.

Wednesday
ANDREW ANTHONY MARCHETTI. Ectopic pregnancy.
CURTIS LESTER MENDELSON. Management of labor in cardiac disease.
JOHN T. COLE and BRUCE WILLIAMS. Clinical application of our knowledge of Rb factor; a report of two transfusion deaths due to Rh incompatibility.
ARTHUR VOSE GREELEY. Selective conservative management of endometriosis.

Thursday
HENRICUS JOHANNES STANDER—9. Gynecology operative clinic.
JAMES AITKEN HARRAI—9. Obstetrical operations.
CHARLES MORDECAI McLANE—2. Stenility.
ROBERT GORDON DOUGLAS—2. Rupture of the uterus. Experiences in the Lying-In Hospital since 1890.
ROBERT GORDON DOUGLAS and R. LANDSMAN—2. Recent experience in the reduction of morbidity and puerperal infection in cesarean section.
WILLIAM GIVEN—2. Carcinoma of the cervix.

Friday
ANDREW ANTHONY MARCHETTI—9. Operative clinic.
HOWARD SHELD McCANDLISH—9. Obstetrical operations.
JOHN T. COLE and FORBES DELANEY. Transverse presentation of vaginal smears.
ANDREW ANTHONY MARCHETTI—2:30. Clinical significance of vaginal smears.
CARL THEODORE JAVERT—2:30. Combined clinical procedure for anteroversion of retroverted uteri.
WILBUR DIXON—2:30. Management of face presentation.
FRANK SMITH—2:30. Missed abortion.

MANHATTAN EYE, EAR AND THROAT HOSPITAL

Monday
G. BONNOCCOLTO—2. Slit lamp demonstration.
HERBERT MAURICE KATZIN—2. Demonstration corneal grafting technique on rabbits.

CHARLES HUGH BRANIGAN—3. Demonstration of cases of cataract surgery complicated by glaucoma.

Tuesday

WALTER GUERNSEY FREY—9. Surgical treatment of ptosis of lids; operation and end-results.

FRANK CONRAD KEIL—2. Surgical treatment of strabismus; operations and end-results.

FRANK CONRAD KEIL, JR. and MISS E. KNAUBER—2. Orthoptic clinic.

Wednesday

ARTHUR LINKS—9. Demonstration of anisokonia.

MURRAY A. LAST—9:30. Plastic operations of eye.

FERDINAND L. P. KOCH—9:30. Demonstration glaucoma clinic; late results of glaucoma surgery.

HERBERT MAURICE KATZIN—10. Demonstration of corneal grafting technique on rabbits.

RICHARD TOWNLEY PATON and HERBERT MAURICE KATZIN—2. Demonstration of corneal grafting technique; corneal research laboratory.

DAVID HENRY WEBSTER—2. Cataract surgery.

ANDREW ANDERSON EGGSTON and A. B. PAUL—2. Allergy in ophthalmology.

JOSEPH LAVAL—3. Eye pathology; demonstration microscopic sections.

Thursday

G. BONNOCCOLOTO—9. Surgery; cataract extraction; corneal transplant; dacryocystorhinostomy.

FRANK CONRAD KEIL, JR.—10. Laboratory demonstration bacteriology of the eye.

RICHARD TOWNLEY PATON—2. Surgery; corneal graft.

MAURICE LENZ, CLARA LOWENHERZ OKRAJNETZ—2. Radiation therapy in ophthalmology.

RICHARD TOWNLEY PATON—3. Demonstration of post-operative corneal graft cases.

Friday

HERBERT MAURICE KATZIN—10. Demonstration corneal grafting technique on rabbits.

FRANK CONRAD KEIL, JR., and MISS E. KNAUBER—2. Orthoptic clinic.

MANHATTAN EYE, EAR AND THROAT HOSPITAL OTOLARYNGOLOGY

Monday

WILLIAM RICHARD CASHION. Biplane fluoroscopy and laminagraphy.

Tuesday

WILLIAM BREWSTER ALLAN and ALFRED SCHATZNER—9. Nasal plastic operation.

MISS WHITEHURST and MRS. NERENBERG—9:30. Demonstration; audiometry; selection and fitting of hearing aids; retraining residual hearing.

DAVID SYLVESTER CUNNING—10. Demonstration of post-operative cases of laryngectomy; esophageal voice training.

DANIEL SYLVESTER CUNNING—2. Operation: laryngectomy.

ANDREW ANDERSON EGGSTON and DANIEL SYLVESTER CUNNING—3. Clinicopathological demonstration; malignancy of the larynx.

Wednesday

MARVIN FISHER JONES—9. Fenestration: operation and demonstration of postoperative cases.

ANTHONY NIGRO—10. Operation for polypoid sinusitis and demonstration of postoperative cases.

DANIEL SYLVESTER CUNNING—1:30. Bronchoscopic clinic; diagnosis and treatment.

ANDREW ANDERSON EGGSTON and A. B. PAUL—2. Allergy in otorhinolaryngology; demonstration of cases and testing technique.

W. H. TURNLEY and G. S. RYAN—2. Tonsil surgery.

Thursday

JOSEPH DOMINIC KELLY—10. Demonstration of results in cases of arytenoidectomy.

MAURICE LENZ and CLARA L. OKRAJNETZ—2. Results of radiation in laryngeal tumors.

HENRY DAVID TATLER—2. Demonstration of radiation of hypertrophied lymphoid tissue of nasopharynx.

MARVIN FISHER JONES—2. Operation: fenestration.

JOSEPH DOMINIC KELLY—2. Operation: arytenoidectomy.

Friday

MISS WHITEHURST and MRS. NERENBERG—9:30. Demonstration; audiometry, selection and fitting of hearing aids; retraining residual hearing.

MEMORIAL HOSPITAL

Monday

Operative Clinics—8.

FRANK E. ADAIR and staff. Breast tumors.

GEORGE E. BINKLEY and staff. Rectal tumors.

BRADLEY L. COLEY and staff. Bone tumors.

HAYES E. MARTIN and staff. Intraoral tumors.

GEORGE T. PACK and staff. Gastric tumors.

CORNELIUS P. RHOADS—2. Steroid patterns in neoplastic diseases.

HAYES E. MARTIN—2:30. Late results in cancer of mouth and pharynx.

WILLIAM L. WATSON—3. Intrathoracic tumors.

FRANK W. FOOTE, JR. and LEO MARINELLI—3:30. Radio iodine in diseases of the thyroid.

F. HOMBURGER—4:30. Protein and carbohydrate metabolism in cancer cases.

Tuesday

Operative Clinics—8.

FRANK E. ADAIR and staff. Breast tumors.

HAYES E. MARTIN and staff. Intraoral tumors.

GEORGE T. PACK and staff. Gastric tumors.

HOWARD C. TAYLOR and staff. Gynecologic tumors.

WILLIAM L. WATSON and staff. Intrathoracic tumors.

HOWARD C. TAYLOR, JR.—2. End-results in cancer of cervix uteri.

FRANK W. FOOTE, JR.—2:30. Early cancer of cervix uteri.

FRANK E. ADAIR—3:00. Hormone therapy in cases of advance mammary cancer.

FRED W. STEWART—3:30. Common errors in cancer diagnosis. Pathological aspects.

DAVIS KARNOFSKY and JOSEPH H. BURCHENAL—4:00. Use of nitrogen mustard in selected types of neoplastic disease.

Wednesday

Operative Clinics—8.

FRANK E. ADAIR and staff. Breast tumors.

GEORGE E. BINKLEY and staff. Rectal tumors.

BRADLEY L. COLEY and staff. Bone tumors.

HAYES E. MARTIN and staff. Intraoral tumors.

HOWARD C. TAYLOR and staff. Gynecologic tumors.

LYDD F. CRAVER—2. Late results in Hodgkin's disease.

GEORGE T. PACK—2:30. Transthoracic cardiotomy for gastric cancers.

GEORGE E. BINKLEY—3. Abdominoperineal resection.

Douglas A. SUNDERS—3:30. Rectal lesions discovered in supposedly normal individuals in a cancer prevention clinic.

SURGERY, GYNECOLOGY AND OBSTETRICS

JULES C. ABELS—4:00. Postoperative management of cases of gastrointestinal malignancies.

Thursday

ROBERT S. SHERMAN—10. Round table roentgenographic conference.
HELEN Q. WOODARD—2. Effect of radiation on normal and neoplastic bone.
BRADLEY L. COLEY—2:30. Analysis of late results.
ARCHIE L. DEAN—3. Treatment after bladder operations.
GEORGE T. PACK—3:30. End-results in malignant melanoma.
SOPHIE SPITZ—4. Infantile neuroangioma—their confusion with malignant melanoma.

Friday

Operative clinics—8.
FRANK E. ADAIR and staff. Breast tumors.
HAYES E. MARTIN and staff. Intraoral tumors.
GEORGE T. PACK and staff. Mixed tumors.
HOWARD C. TAYLOR and staff. Gynecologic tumors.

MONTEFIORE HOSPITAL

Tuesday

SAMUEL SILBERT—2. Mid-leg amputations for gangrene in the diabetic.
Sylvan Lewis Haas—9. Orthopedic surgery in arthritic and paralytic diseases.

Wednesday

Thursday

Isidor Kross—2. Chest surgery—operative and dry clinic.

Friday

SAMUEL STANDARD—2. Physiological derangements in organic disease of the intestinal tract—end-results of surgery.
ARTHUR HARVEY GLICK—2. Errors in diagnosis in tumors of the large bowel.
DANIEL LASZLO—2. Conference on neoplastic diseases and demonstration.

MOUNT SINAI HOSPITAL

Monday

Gynecological clinic—8:30.
MORRIS AARON GOLDBERGER. Parametrial fixation operation (Fothergill).
MORRIS AARON GOLDBERGER. Result of parametrial fixation operations; postoperative follow-up (ten years).
JOSEPH ARNOLD GAINES. Conservative surgery for pelvic endometriosis.
EMANUEL KLEMPNER. The value of the 24 hour pregnancy test: A review of 1,000 cases.
ARTHUR MAXWELL DAVIES. The clinical value of hysterography.
ROBERT ISADORE WALTER. The management of the menopause.
Neurological Surgery—2.
ABRAHAM KAPLAN. Long time follow-up in some neurosurgical cases (case presentations).
B. SCHLESINGER. Correlation of x-ray findings and clinical picture.
IRA COHEN. Dumbbell tumor of the spine.
S. GROSS. Cranioplasty, motion picture demonstration

Tuesday

JOHN HARRY GARLOCK. Anterior resection of the rectum; colectomy for ulcerative colitis.

JOHN HARRY GARLOCK, LEON GINSBURG, SAMUEL HARRIS, OLD KLEIN, AMEL GLASS, GABRIEL PARKIN, SELEY. Dry clinic and case presentations.
Orthopedic clinic—2.
ROBERT KORN LIPPMANN, ALBERT JACOB SCHIN, EDGAR MILTON BICK. Operative and dry clinic.

Wednesday

Thoracic surgery—8:30.
ARTHUR SIGMUND TOUROFF. Operation for patent ductus arteriosus.
HAROLD NEUHOF. Intramuscular heparin (concentrated) therapy in the prevention of postoperative thrombosis and embolism.
Motion picture demonstration Technique of operation for clotted hemothorax.
ARTHUR SIGMUND TOUROFF. Results of operative treatment of traumatic thoracic lesions in civilian practice and embolism.
ERNEST EMANUEL ARNHEIM. Operative results in pericardial surgery.
EDWARD E. JEMERIN. Results of surgical treatment of perforation of the esophagus.
IRVING ARTHUR SAROT. Results of conservative surgical treatment of chronic pulmonary abscess.
Clinic on ophthalmology—2.
DAVID LAMBERT, HENRY MINSKY, JOSEPH LAVAL, DAVID WEXLER. The surgical treatment of glaucoma—operative clinic and dry clinic of operated cases.

Thursday

Surgery of the stomach and duodenum: Operative clinic—8:30.
RALPH COLP. Supradiaphragmatic vagotomy for duodenal ulcer; subtotal gastrectomy and infradiaphragmatic vagotomy for duodenal ulcer with stenosis.
Dry clinic
FRANK HOLLANDER. Physiologic differences between gastric and duodenal ulcers.
LEONARD DRUCKERMAN. Palliative gastrectomy in selected cases of chronic gastric ulcer.
PERCY KLINGENSTEIN. Problems in the treatment of gastrojejunal fistula.
SIGMUND MAGE. Follow-up results in subtotal gastrectomy for gastric and duodenal ulcer.
STEPHEN ROSENACK. The advantages of jejunostomy for jejunal alimentation.
Ear, nose and throat clinic—2.
Inflammatory and neoplastic diseases of the frontal sinuses.
Carcinoma of the larynx and results, treatment by radiation therapy.
Operative and dry clinic.
RUDOLPH KRAMER, MORRIS BENDER, IRVING BRICE, GOLDMAN, JOSEPH DRUSS, SAMUEL ROSEN and staff

Friday

Genitourinary surgery—8:30. Operative clinic.
LEO EDILMAN. Kidney operation.
GORDON DAVID OPPENHEIMER. Carcinoma in a horseshoe kidney (dry clinic).
MOSES SWICK. Bladder neck obstruction in young individuals.
WILLIAM MENCHER. Perirenal insufflation.
H. EVANS LEITER. Enuresis due to ectopic ureter.

METROPOLITAN HOSPITAL

Monday

Neurosurgery—2.
I. W. OLJENICK.

Tuesday

EDWARD J. McCABE, KENNETH C. PEACOCK and WILLIAM GREENWALD—9. Hemorrhage, perforation and the indications for surgery in peptic ulcer.

CHARLES A. HALBERSTAM, GEORGE HERLITZ and EUGENE FIERRO—11. Diagnosis and management of intestinal obstruction.

Urology—2.

ALFRED HUNT and LEONARD P. WERSHUB. Total perineal prostatectomy.

GEORGE R. NAGAMATSU. Plastic operations for ureteropelvic junction obstruction.

SPRAGUE CARLETON. General discussion.

Wednesday

HAROLD E. CLARK, WALTER GRAY CRUMP and WALTER L. MERSHEIMER—9. Colon surgery; Indications, methods and end-results.

H. B. SAFFORD and JOHN E. TRITSCH—10. Gynecology staff with presentation and consideration of problem cases.

Thoracic surgery—2.

SAMUEL A. THOMPSON and staff. Value of cavernostomy in tuberculosis.

Thursday

STEPHEN CHILIAN, LOUIS M. PALERMO and WILLIAM L. PRIMACOVE—9. Echinococcus cyst; diagnosis and management.

LOUIS R. KAUFMAN, LINN J. BOYD and CHRISMAN G. SCHERF—10. Surgery of hypertension; Indications, technique and end-results.

JOHN F. FORD and DAVID M. MAYER—10. The problem in skin grafting for thrombophlebitis.

HARRY BAROWSKY—11. Round table discussion of abdominal diagnosis; gastroscopy.

LEONARD P. WERSHUB—11. Perinealoscopia.

JOHN HERRLIN and staff—11. Peritoneal tap and x-ray diagnosis.

MILTON JOHN WILSON and staff—2. Demonstration of end-results in spine and hip injuries.

Friday

SAMUEL THOMAS GLASSER, JOSEPH A. SILEO, and G. ADLER—9. Peripheral vascular diseases: end-results in refrigerating anesthesia; amputation; lumbar sympathectomy; multiple nerve section; lumbar ganglion block; intra-arterial penicillin.

SAFFORD and JOHN E. TRITSCH—10. Gynecology staff with presentation and consideration of problem cases.

JOHN F. FORD and DAVID M. MAYER—10. The problem in skin grafting for thrombophlebitis.

K. LANGE, LINN J. BOYD, DAVID O. WEINER, and ALBERT LESSER—10:30. Frostbite, its physiology and morphologic pathology and the prevention of subsequent gangrene.

NEW YORK EYE AND EAR INFIRMARY
OTOLARYNGOLOGY

Demonstrations and lectures daily by EARL FREDERICK LIMBACH, MAXWELL DONNELL RYAN, JAMES MORRISSET SMITH, JAMES SWIFT HANLEY, STUART LESSLEY CRAIG.

OPHTHALMOLOGY

Demonstrations and lectures daily by WENDELL LOCHHEAD HUGHES, RAYMOND EMORY MEEK, CONRAD BERENS, BRITAIN FORD PAYNE, WILLIS SACKETT KNIGHTON.

THE NEW YORK HOSPITAL

Monday

General surgery—2.

ERNEST WILLIAM LAMPE. Surgical anatomy demonstration: detailed anatomy of hand and wrist as involved in infection and trauma.

Otolaryngology: Operative clinic—2.

ARTHUR PALMER. Reconstructive surgery of the nose.

Tuesday

General surgery—9

GEORGE JULIUS HEUER and staff. Operative and dry clinics

GEORGE JULIUS HEUER. Follow-up study of treatment of peptic ulcer.

CRANSTON WILLIAM HOLMAN. Bleeding peptic ulcer WILLIAM COOPER. Diagnosis of stomach lesions.

EDGAR COOPER PERSON, JR. Gastrojejunocolic fistula WILLIAM BARNES. Carcinoma of the head of the pancreas.

General surgery, dry clinic—2

GEORGE JULIUS HEUER and staff.

WILLIAM DE WITT ANDRUS. Follow-up results. Aneurysm of large vessels.

WILLIAM COOPER. Follow-up results—carcinoma of breast, stomach, colon, rectum.

BRONSON SANDS RAY. Organization of follow-up clinic. Follow-up clinic staff. Demonstration.

ERNEST WILLIAM LAMPE. Surgical anatomy demonstration—anatomy of neck as regards radical neck dissection.

Genitourinary surgery—9.

ERNEST WILLIAM LAMPE. Surgical anatomy demonstration of male perineum.

Otolaryngology: operative clinic—2.

GERVAIS WARD MCAULIFFE. Surgery of the mastoid.

Urology (Cornell)—2.

VICTOR MARSHALL.

E. CRAIG COATS. Results of untreated bladder carcinoma.

VICTOR FRAY MARSHALL. Results of radiation treatment.

MARTIN SPATZ. Autopsy findings.

ARCHIE LEIGH DEAN, JR. Physical factors limiting radiation treatment.

JEREMIAH EDWIN DREW. Results in bladder resection.

ALISTER MATHESON McLELLAN. Results of fulguration and simple excision.

GUSTAVUS ALDRIDGE HUMPHREYS. Results of ureterocutaneous anastomosis.

DAVID H. MACFARLAND. Results of ureterointestinal anastomosis.

MORRIS SCHNITTMAN. Results of cystectomy.

VICTOR FRAY MARSHALL. Summary.

Wednesday

General surgery—2.

ERNEST WILLIAM LAMPE. Surgical anatomy demonstration—anatomy of breast as regards radical mastectomy.

Genitourinary surgery—2.

THOMAS JOSEPH KIRWIN. Operative and dry clinic: perineal prostatectomy.

ROSE HENRI ANDRÉ. Demonstration of spinal anesthesia.

ROY BIGGS HENLINE. Ureteropelvic obstruction.

GEORGE ADOLPH FIEDLER. Absorbable gauze in urologic surgery.

FRANCIS PATTON TWINEM. Case report.

SURGERY, GYNECOLOGY AND OBSTETRICS

ROBERT W. HUNT. True adrenal tumor of kidney.
CYRIL KLOCK CHURCH. Ureteral obstruction in relation to psychosis.

STANLEY LEON WANG. Treatment of bladder tuberculosis with a new instrument and method.

FRANCIS ANTHONY BENEVENTI. Glands in female urethra of the infant.

ALBERT VERGES-FLAQUE. Foreign body in ureter.

THOMAS F. CONROY. Transplantation of ureters.

ALBERTO GENTILE. Case report.

DENNIS ALOVINSY KELLEHER. Case report.

symptoms in urology. Gastroenterological

CECIL HAWES. Case report.

WILLIAM P. DIDUSCH. Demonstration of drawings of interesting urological cases and operations. Motion pictures of urological operations.

Neurology—2.

BRONSON SANDS RAY, HAROLD GEORGE WOLFF, JOSEPH HINSEY. Surgical treatment of cardiac pain.

CHARLES M. BERRY and JOSEPH HINSEY. Studies in regeneration of peripheral nerves.

CHARLES LAMAR NEILL, JR. Intracranial aneurysms.

DONALD SIMON and HAROLD GEORGE WOLFF. Studies of post-traumatic headache.

HERBERT PARSONS. Ruptured disks of the cervical region.

ARTHUR CONSOLE. Sympathetic innervation of the extremities.

BRONSON SANDS RAY. Results of sympathectomy for hypertension.

BRONSON SANDS RAY and staff. Neurosurgical case reports.

Thoracic surgery—9.

GEORGE JULIUS HEUER and staff. Operative and dry clinic.

GEORGE JULIUS HEUER. Constrictive pericarditis.

WILLIAM deWITT ANDRUS. Surgery of mediastinal tumors.

JOHN HAAO ECKEL. Follow-up studies of mediastinal tumors.

HENRY ARNOLD CROMWELL and WILLIAM ALEXANDER BARNES. Clinical value of sputum diagnosis.

Otolaryngology. Operative clinic—2.

SAMUEL F. KELLEY. Surgery of the paranasal sinuses.

Thursday

General surgery—2.

GEORGE JULIUS HEUER. History of operative procedure for acute cholecystitis.

NATHAN CHANDLER FOOT. Pathology of acute cholecystitis.

FRANK GLENN. Surgical treatment of acute cholecystitis.

SAMUEL WILSON MOORE. Complications of acute cholecystitis.

ERNEST WILLIAM LAMPE. Surgical anatomy demonstration—anatomy involved in lumbar and thoracolumbar sympathectomy.

Plastic and faciomaxillary surgery—9.

HERBERT CONWAY. Operative and dry clinic; one stage push back operation for congenitally short palate; results following treatment of carcinoma of the head and neck; case presentations.

E. FREUD. Speech therapy in cases of cleft palate.

CHARLES NEWMAN. End-results following radical breast amputation with split skin grafting.

JAMES DINGWALL. Adult tissue extract in wound healing.

Otolaryngology: Dry clinic—2.

ARTHUR PALMER and associates. Case presentations and postoperative result—laryngofissure, carcinoma of the trum, mastoiditis with petrositis and meningitis acute frontal sinusitis with meningitis.

Ophthalmology: Operative clinic—9.

JOHN McLEAN and staff. Intracapsular cataract. Glaucoma.

Friday

General surgery: Dry clinic—2.

GEORGE JULIUS HEUER and staff.

GEORGE PAPANICOLAOU. Diagnosis of carcinoma from disquanted cells.

FRANK GLENN and DAN CUMMINGS GILL. Clinical results of the use of streptomycin.

SAMUEL WILSON MOORE. Follow-up studies of polyps of the large intestine.

JAMES DINGWALL. Adult tissue extract in wound healing.

ERNEST WILLIAM LAMPE. Surgical anatomy demonstration: anatomy of region involved in lobectomy and pneumonectomy.

Surgery of the bones and joints.

NELSON WARREN CORNELL—9. Operative clinic.

NELSON WARREN CORNELL—2. Dry clinic.

CHESLEY EVAN SMITH. Volkman's ischemic paralysis.

ARTHUR CONSOLE. Threatened Volkman's paralysis prevention by sympathetic block.

PRESTON WADE. Massive only bone grafts for ununited fractures.

BERNARD MAISEL. Table fracture of tibia; conservative treatment.

BROADMAN MARSH BOSWORTH. Fixation of acromioclavicular separation.

NELSON CORNELL. End-results; fracture of neck of femur treated with Moore nails.

Otolaryngology: Operative clinic—2.

THOMAS JOSEPH GARRICK. Surgery of the oropharynx and nasopharynx.

NEW YORK ORTHOPEDIC HOSPITAL

Operative clinics—8.

Monday

Presentation of postoperative patients of many years' follow-up—8.

Tuesday

Operative clinics—8.

Wednesday

Grand rounds with chief surgeon at the New York Orthopedic Dispensary and Hospital, ALAN DEFOREST SMITH

Thursday

Operative clinics—8.

Friday

Out-patient clinic in the dispensary—1:30 p m to 4:30 p m

Monday to Friday

NEW YORK ORTHOPEDIC HOSPITAL FRACTURE SERVICE

Monday

SAWNEY RENARD GASTON—1:30. Problem fractures with follow-up results.

Tuesday

CLAY RAY MURRAY and staff—9. Operative clinic. Fracture follow-up clinic—1:30. X-ray review—4.

Wednesday

- CLAY RAY MURRAY and staff—9. Operative clinic.
 HARRISON LLOYD McLAUGHLIN—1:30. Shoulder cuff injuries and recurrent shoulder dislocations with follow-up results.
 BARBARA BARTLETT STIMSON—3. The low back problem with follow-up results.

Thursday

- CLAY RAY MURRAY and staff—9. Operative clinic.
 FREDERICK MERWIN SMITH—1:30. Complicated elbow fractures with follow-up results.
 STEPHEN SYLVESTER HUDACK—3. Collagen and organic salt; combination for bone displacement.

Friday

- Fracture Service Grand Rounds and Conference; Significance of blood volume studies in trauma—9.
 CLAY RAY MURRAY—2:30. Role of sympathetic system in the surgery of trauma.

NEW YORK POST-GRADUATE HOSPITAL

Monday

- Operative clinic—9. Diseases of gall bladder and bile ducts.
 RUPERT FRANKLIN CARTER—11. Dry clinic. Follow-up results.
 JAMES WILLIAM HINTON—2. Operative clinic.

Tuesday

- Follow-up results—9.
 GEORGE ANOFOL—10:30. Operative clinic.
 GUSTAV AUFRLOT—10:30. Case illustrations in operative procedures in plastic surgery.
 WALTER TAYLOR DANNREUTHER—2. Operative clinic; gynecology.

Wednesday

- Operative clinic—9. Neurosurgery.
 JOHN ARTHUR MACLEAN, JR.—9. Follow-up clinic patient illustration.
 BERNARD MARRAFFINO—11. Value of immediate and delayed cholangiography in the surgical management of common duct disease. Case illustration.
 Follow-up results in advanced common bile duct lesions. Case illustrations—12.
 CHARLES GORDON HEYD—2. Operative clinic; General surgery.

Thursday

- HERBERT WILLY MEYER and ROBERT HAYWARD KENNEDY—9. Operative and dry clinic on problems in surgery of tumors of breast, head, and neck.
 HENRY HAUSMAN RITTER—2. Operative and dry clinic in traumatic surgery.
 Ophthalmology—2.
 RUDOLPH AEBLI and HAROLD BROWN. Eye muscle operations.

Friday

- CARNES WEEKS—9. Operative clinic; Surgery in hypertension.
 GERALD HILLARY PRATT—10:30. Operative clinic; diseases of the vascular system.
 THOMAS HENDRICK RUSSELL—2. Operative clinic; general surgery.

PRESBYTERIAN HOSPITAL

Monday

- Dry clinic—2.
 EDWARD LEE HOWES. Experimental production of carcinoma of stomach.
 HUGH AUCHINCLOSS. Twenty year follow-up in carcinoma of the breast.

ARTHUR PURDY STOUT. The relation of chronic cystic disease to cancer of the breast.

CUSHMAN DAVIS HAAGENSEN. The problem of early diagnosis in cancer of the breast.

MAURICE LENZ. Roentgentherapy of cancer of the breast in non-operated cases and as a preoperative and postoperative treatment.

CUSHMAN DAVIS HAAGENSEN. Surgery versus radiation in cancer of the breast.

Tuesday

Dry clinic—2.

HAROLD DORTCH HARVEY. Blood volume studies in surgical patients.

OCTA CHARLES LEIGH. Physiological studies in injuries due to cold.

SIDNEY CHARLES WERNER. Use of amino acids in pre-operative and postoperative nutrition.

EDWARD BALDWIN SELF. Serum versus plasma.

FENNELL PARRISH TURNER II. Use of dextran in surgical patients.

JOHN SCUDDER. Experience with human albumin.

Thursday

Dry clinic—2.

LOUIS BAUMAN. Diagnosis of pancreatic disease.

WILLIAM BARCLAY PARSONS. Surgery of tumors of the ampulla of Vater and head of pancreas.

ROBERT HARE ELLIOTT, JR. Experiences with propacil in thyroid diseases.

EDWARD LEE HOWES. Use of streptomycin and sulfonyl to prevent wound infection.

RUDOLPH NICHOLAS SCHULLINGER. Observations on acute appendicitis at Presbyterian Hospital 1916-1946.

FRANK LAMONT MELENY. Recent laboratory and clinical experiments with the new antibiotic bacitracin.

Friday

Dry clinic:

VIRGINIA KNEELAND FRANTZ. Hemostasis with absorbable gauze.

JOHN HENDLEY BLAKEMORE. Wiring of aneurysms

ARTHUR MUNN HANFORD. Carcinoma of the tongue, follow-up results.

LAWRENCE WELLS SLOAN. Follow-up results in thyroid operations.

ROSS GOLDEN. Pathological physiology in the intestine induced by adhesions.

HENRY SAGE COOPER. Practical considerations in intestinal obstruction.

PRESBYTERIAN HOSPITAL
BABIES HOSPITAL*Friday*

Members of the staff—9. Operative clinic.

Presentations of current cases—11.

Dry clinic, follow-up studies—2.

EARL C. TAYLOR. Appendicitis.

BRUCE MACLEAN HOGG. Intussusception.

LOUIS MARCEL ROUSSELOT. Banti's syndrome.

GEORGE HUMPHREYS II. Esophageal atresia.

EDWARD BALDWIN SELF. Acute osteomyelitis.

PRESBYTERIAN HOSPITAL
NEUROLOGICAL INSTITUTE*Monday*

FRITZ CRAMER (time to be announced). The surgical treatment of syringomyelia; the surgical treatment of the neuralgias of the facial and vagus nerves; cases of bilat-

SURGERY, GYNECOLOGY AND OBSTETRICS

eral parasagittal meningeomas with excision of the longitudinal sinus.

CLEMENT BUCHANAN MASON (time to be announced). Experiences in the removal of metallic foreign bodies from the brain with the use of a Berman locator.

LESTER ADRIAN MOUNT (time to be announced). Premature synostosis of the sutures of the cranial vault—a plea for early recognition and early operation. A new type of operative procedure; congenital dermal sinus, lumbosacral, thoracic, and occipital, associated with subdural abscess, meningitis or abscess of the spinal cord.

Tuesday

BYRON POLK STOOKEY (time to be announced). Dermoid tumors of the spinal cord.

JOHN EDWIN SCARFF and J. LAWRENCE POOL (time to be announced). Factors contributing to massive involuntary spasm in paraplegic patients; report on the treatment of hydrocephalus in infants.

EDWARD B. SCHLESINGER (time to be announced). Curative treatment of spastic states.

Thursday

PRESBYTERIAN HOSPITAL
THE INSTITUTE OF OPHTHALMOLOGY

Monday

ALGERNON BEVERLY REESE and staff—2. Surgical procedures in glaucoma and cataract.

Tuesday

GORDON MURPHY BRUCE and staff—2. Operative clinic.

RAYMOND CASTROVIEJO—2. Surgery of the cornea.

Wednesday

JOHN HUGHES DUNNINGTON—2. Surgery of the extraocular muscles and intraocular operations.

ROOSEVELT HOSPITAL

Monday

Traumatic and reconstructive surgery of the hand—2.

HENRY AUGUSTUS KINGSBURY. Early treatment and management of injuries (illustrated).

R. STERLINO MUELLER. Late repair and restoration of injured flexor tendons (illustrated, case presentations).

CONDUCT WALKER CUTLER, JR. Reconstructive surgery of bones of the hand (illustrated).

Tuesday

Surgical treatment of lesions of the colon—9.

HENRY WISDOM CAVE. Subtotal colectomy (operation) for ulcerative colitis. Rounds and demonstration of patients.

Surgical treatment of lesions of the colon—2.

FREDERICK HENRY AMENDOLA. Results of resection of tumors of the colon, case reports (illustrated).

HENRY WISDOM CAVE. Sequelae, complications, and late results of the surgical treatment of ulcerative colitis. (Motion pictures of technique of ileostomy and colectomy. Presentation of cases showing late results.)

WALTER WILLIAM BRANDES. Pathology of ulcerative colitis. Gross and microscopic specimens (illustrative lantern slides).

Wednesday

Cancer of the breast—9.

WILLIAM CRAWFORD WHITE. Radical mastectomy (operation). Rounds, presentation of cases and illustration of late results.

WILLIAM HENRY CASSEBAUM. Presentation of cases illustrating various fractures and their complications (illustrations).

MARION BECKETT HOWORTH. Management of unusual fractures of the femoral neck. Case presentations (illustrations).

JAMES EDWIN THOMPSON. Compound fracture at the knee joint (illustrated). Case reports.

Thursday

Malignant disease of the female pelvic organs—9.

WILLIAM PATRICK HEALY. Hysterectomy for cancer results in cancer of the female pelvis: discussion and demonstration of results of surgery and irradiation.

Surgery of the genitourinary tract—2.

SIMON ANTHONY BEISLER. Suprapubic prostatectomy (operation). Presentation of patients illustrating results of urological procedures.

Friday

Surgery of the stomach—9.

HOWARD A. PATTERSON. Subtotal gastrectomy (operation). Presentation of cases illustrating late results of gastric surgery, with particular reference to gastric tumors (illustrated).

WALTER WILLIAM BRANDES. Demonstration of stomach tumor specimens.

GRANT PALMER PENNOYER. The rôle of a vascular clinic in a general hospital (illustrated). Demonstration of cases.

DAVID MERRILL WEEKS. The observed effect of various drugs on intestinal activity (moving picture demonstration).

ST. LUKE'S HOSPITAL

Monday

GEORGE FRANCIS HOCH. 2. Congenital ureterectasis.

JOHN ARTHUR TAYLOR. 2:30. Testicular tumors.

CRAIG COATES. 3. Bladder tumors.

JAMES R. WAUGH. 3:30. Uteropelvic obstruction.

WESTLEY MARSHALL HUNT. Bronchoscopic diagnosis of carcinoma of lung.

JOHN WINSTON FOWLER. The use of penicillin in otolaryngological surgery.

Tuesday

WILLIAM FRANK MACFEE and staff—8:30. Operations.

ALEXANDER WILLIAM ADA—11. Review of surgery of stomach and duodenum.

FRED PALMER SOLLEY—11:30. Case reports—3 cases subtotal gastrectomy for massive hemorrhage.

JOHN COOPER—12. Experience with curative in prolonged operations.

MORRIS KELLOGG SMITH and GEORGE MUNRO GOODWIN—reference to the use of surgery for toxic goiter with special reference to the use of thiouracil.

MATHEW CLEVELAND—2. Hazards of external fixation in skeletal traction.

DAVID MARSH BOSWORTH—2:30. Difficult fractures.

Management and end-results.

FRED THOMPSON—3. End-results in 100 trochanteric fractures of the femur.

BORIS PETROFF—4:30. Neurogenic bladder.

Wednesday

WILLIAM FRANK MACFEE and staff—8:30. Operations.

WILLIAM FRANK MACFEE—11. Carcinoma of colon at rectosigmoid junction, management.

EDWARD JOSEPH DONOVAN—11:30. Ten year study of carcinoma of colon exclusive of rectum.

PAUL CALHOUN MORTON—12. Polyps of rectum and sigmoid, management and treatment.

- BENJAMIN RICE SHORE, JR.—12:30. Carcinoma of breast. Ten year follow-up report.
JOHN WINSTON FOWLKES and staff—2. Operations or ward rounds.
JOHN WINSTON FOWLKES—3. Penicillin as an adjunct to surgery in otolaryngology.
WESLEY MARSHALL HUNT—3:30. Bronchoscopic diagnosis in carcinoma of lung.

Thursday

- WILLIAM FRANK MACFEE and staff—8:30. Operations.
MORRIS KELLOGG SMITH—11. Vascular surgery in war injuries.
FRANKLIN STAFFORD WEARN—11:30. Pulmonary embolism.
ALEXANDER WILLIAM ADA—12. End-results in lobectomy for bronchiectasis; case report; constrictive pericarditis (calcified), operation and end-result.
JOHN JACOB WESTERMANN, JR.—12:30. Case reports. Surgery of ulcerative colitis.

Friday

- WILLIAM FRANK MACFEE and staff—8:30. Operations.
JOHN WEST—11. Inguinal hernia, study of cases and end-results.
WILLIAM BERRY—11:30. Case report, carcinoma ampulla of Vater, Operation and end-result.
HERBERT PARSONS—12. Penetrating head injuries war experience.
JOHN WEST—12:30. Case report, lymphosarcoma of small intestine with metastases to extremity.
WALTER GURNEY FREY—2. Blood pressure variations in ophthalmological operations under local anaesthesia.
WALTER GURNEY FREY and staff—2:30. Operations or ward rounds.

ST. VINCENT'S HOSPITAL

Tuesday through Friday

- RAYMOND PETER SULLIVAN and GEORGE R. STUART and staff—9. Surgical operations.
JOHN FRANCIS McGRATH and staff—9. Gynecological operations.
C. G. DE GUTIERREZ-MAHONEY and staff—9. Neurosurgical operations.

Monday

- Dry clinic—2. Hodgkin's disease symposium.
JOHN FRANCIS KEATING—Clinical findings.
WILLIAM WALLACE MAVER. X-ray findings and x-ray therapy.
ANTONIO ROTTINO. Pathological findings.
GLADYS CAMERON and COATA GRAND. Experimental studies.

Tuesday

- Dry clinic—2. Surgical.
RAYMOND PETER SULLIVAN. Biliary tract reconstruction.
FRANK JOSEPH MCGOWAN. What civilian surgery has learned from the war.
DANIEL A. MULVIHILL. Decortication of the pleura—a new operation for non-expandable lungs.
CONSTANTINE JOSEPH MACGUTHRIE, JR. Pancreatitis.
BERNARD D. HANNAN. Acute cholecystitis, immediate versus delayed operation.

Wednesday

- Dry clinic—2. Neurosurgical.
J. T. DANIELS. A new method for reducing extensive nerve defects.
A. GRINO. Morphology of the oligodendroglia demonstrated by a new method.
C. G. DE GUTIERREZ MAHONEY. The treatment of phantom limb pain.
W. G. KOHN, JR. Care and rehabilitation of the paraplegic patient.

Thursday

- Dry clinic—2. Surgical.
GEORGE R. STUART. Résumé of cancer studies over 4 years.
GEORGE VAN GILLUWE. Advantages of the use of compressed air in anesthesia.
EDWARD VICTOR DENNEEN. Fractures of both bones of the leg.
MAURICE CULMER O'SHEA. Fractures of the os calcis—200 cases.
T. M. HOWLEY. Carcinoma of the kidney.

Friday

- Dry clinic—2. Gynecological.
JAMES PATRICK HENNESSY. Cesarean section.
ALEXANDER HUNTER SCHMITT. Multiple cesarean sections.
THOMAS EUGENE LAVELL. Ovarian neoplasma.
BERNARD JOSEPH PISANI. The program for gynecological care in the Veterans Administration.
Dry clinic—2. Otolaryngological.
JOHN MARION LORE and staff. Speech clinic, etc.

WOMAN'S HOSPITAL

Monday, Wednesday and Friday

- ALBERT HERMAN ALDRIDGE, LEE MAIDMENT HURD, WILLIAM T. KENNEDY, and RALPH A. BARRETT—8:30 a.m. to 12:00 noon. Operative clinics.
Demonstrations: Treatment of neoplasms of the pelvic organs, uterine displacements, birth injuries. End-results of the procedures will be discussed.

SURGERY, GYNECOLOGY AND OBSTETRICS

PRELIMINARY CLINICAL PROGRAM

BROOKLYN. LONG ISLAND HOSPITALS

BROOKLYN EYE AND EAR HOSPITAL

Wednesday
Daily operative clinic.
Demonstrations by surgeons of the staff of the Brooklyn Eye and Ear Hospital.
Late results in detachment of retina.
Late results in cataract extraction.
Late results in fenestration.
Late results in dacryocystorhinostomy.

Thursday
Daily operative clinic.
Demonstrations by surgeons of the staff of the Brooklyn Eye and Ear Hospital.
Late results in facialmaxillary surgery.
Late results in laryngectomies.
Late results in glaucoma surgery.
Angioscotometry exhibit.

CUMBERLAND HOSPITAL

Monday
General surgery—2. Discussion of postoperative complications. Use of sulfanamides in acute abdomen. Pre-operative and postoperative treatment in gastrointestinal surgery. Advantages of Miller Abbott tube in small bowel obstruction. Late results in the surgery of gastrointestinal malignancy with pathological demonstration

Tuesday
Obstetrics—gynecology—9
SAMUEL LUBIN and staff. Operations.
CHARLES H. LOUGHRAN and staff. Preoperative and postoperative care of gynecological patients.
HERBERT T. WIKLE. Proctidemia, demonstration of technique for its relief, 15 year follow-up.
Late results in pelvic malignancy.
Obstetrics—gynecology—2.
Gynecological abnormalities in youth—2 case reports.
SILK H. POLAYES. Isolimmunization with A and B factors in erythroblastosis fetalis.
LESLIE H. TISDALL. Importance of blood and blood derivatives in obstetrics.
RICHARD WALTMAN. Conservative management of abortions. Thrombophlebitis after pelvic operations.
CHARLES H. LOUGHRAN. Bacillus welchii postpartum infection—late results.

Wednesday
General surgery—9.
JOHN J. GAINES and staff. Gastrectomy for carcinoma of the stomach with discussion of late results.
JOHN A. TRANT and staff. Ward rounds, discussion of the surgical gall bladder with late results.
HOWARD T. BLAIR. Ward rounds with discussion of surgery in large bowel malignancy. Retroperitoneal teratoma with slides.
General surgery—2.
JOSEPH I. ANTON. Arteriovenous fistula with follow-up.
SILK H. POLAYES. Granuloma inguinale (venereum) of uterus with follow-up.
WILLIAM H. FIELD. Thoracic surgery in general hospital.
JOHN A. TRANT. Common duct atresia.
SAUL F. LIVINGSTON. Congenital esophageal atresia.
MARTIN H. LUTZ. Traumatic evisceration with follow-up.

Thursday
Fractures and other traumas—9.
LEO FASKE and staff. Pinning for femur neck fracture.
Late results in fracture of femur neck.
JOSEPH I. ANTON. Traumatic abdomen.
Ward rounds with x-ray studies of various types of fractures.
Fractures and other traumas—2.
JOSEPH I. NEVINS and staff. Non-union, late results and general discussion.
Ward rounds with demonstration of apparatus in use.
Gadgets and their use in fracture treatment.
FRANK TURNEY. Head injuries, late results.

Friday
Urology—9.
HOWARD T. LANGWORTHY and staff. Carcinoma of prostate. Orchietomy for prostatic metastases—late results.
LEO S. DREXLER and staff. Carcinoma of bladder and transplantation of ureter—late results.
General surgery—2.
Thrombophlebitis after pelvic operations. Late results in thrombophlebitis and phlebotrombosis. Embolus during riding embolus of abdominal aorta. Convulsions during anesthesia—late results. Late results in surgical jaundice.

HOUSE OF ST. GILES THE CRIPPLE

Wednesday
JOSEPH B. L'EPISCOPO, JOSEPH GIANQUINTO, CARVELLO VITALE. Orthopedics.
Dry clinic. Abduction traction splint for congenital dislocation of hip. Demonstration of cases. Follow up clinic on foot reconstruction for poliomyelitis unstable feet—results following Hoke, Naughton-Dunn, Lefort and astraglectomy stabilizations. Shoulder fusion for poliomyelitic flail shoulders—5 year follow-up. Demonstration of cases. Follow-up on stabilization of cases. Recurrent club foot. Demonstration of cases following resection of head of talus plus transplantation of anterior tibial tendon.

JEWISH HOSPITAL

Tuesday
Operative clinic—8.
LOUIS BERGER and staff.
Dry clinic—10.
LOUIS J. MORSE and JACOB S. BARR. Fascial transplant in repair of large incisional hernia.
ALFRED L. SHAPIRO. Configuration and variations of the duodenal choledochal and middle colic arteries.
LEWIS E. SCROTTENFELD. Bacillus welchii infections of the biliary tract.
BERNARD PINES. Postoperative obstruction of the bile duct treated with vitalium tube.
HYMAN L. BERSON and PAUL W. ASCHNER. Pitfalls in the diagnosing and surgical therapy of obstructive jaundice.
BENJAMIN M. BERNSTEIN. Critical review of peptic ulcer therapy.
DAVID FAABER. Carcinoma of small bowel.

- SAMUEL ACHS. Bowel perforation with Miller Abbott Tube.
 LOUIS BERGER. Restoration of alimentary continuity in carcinoma of rectum.
 Operative clinic—1:30.
 ISADORE M. TARLOV. Plasma clot suture of peripheral nerve.
 Neurosurgical dry clinic—3:30.
 JOSEPH H. SIRIS and staff.

Wednesday

- Operative clinics—8.
 HENRY W. LOURIA and staff.
 RUDOLPH NISSEN and staff.
 Dry clinic—10.
 IRVING M. PALLIN. Curare and endotracheal anesthesia in poor risk patients.
 EDWARD HIRSCH and LEO LOEWE. Treatment of post-operative phlebothrombosis with subcutaneous heparin.
 SAUL F. LIVINGSTON. Bleeding nipple.
 LEW A. HOCHBERG. Paradoxical respiration; its cause, consequence, and treatment.
 RUDOLPH NISSEN. Endorhaphy as surgical procedure in the treatment of giant air cysts of the lung.
 VICTOR WORONOV. The use of thiouracil in the surgical management of toxic goiter.
 ARTHUR A. WEINBERG. The diagnosis and surgical treatment of thyroiditis.
 FRANK TELLER. Malignant tumors of the thyroid gland—diagnosis, management and end-results.
 HENRY W. LOURIA. Surgical management of goiter.
 Dry clinic: Orthopedics—2.
 S. A. BERNSTEIN. Operative correction of Hammer toes by resecting the middle phalanx.
 MORRIS T. KOVEN. Pre-standing cases of congenital subluxation of the hip.
 LOUIS S. NELSON. The conservative management of slipping of the upper femoral epiphysis.
 BENJAMIN KOVEN. The use of the Austin Moore plate and its modifications in high osteotomy of the femur.
 LT. COL. JOSEPH E. MILGRAM. Reconstruction Key gliding mechanisms of the upper extremity.
 A. E. SOBEL and BENJAMIN KRAMER. Composition of bone in relation to blood and diet.
 BERNARD S. EPSTEIN. The application of laminography to some orthopedic problems.

Thursday

- Operative clinics—8.
 PAUL W. ASCHNER and staff.
 LEO S. SCHWARTZ and staff.
 Obstetrics—gynecology—10.
 E. GOLD. Pelvic drive in obstetrics.
 ISIDORE DAICHMAN and WILLIAM POMERANCE. Extra-peritoneal cesarean section.
 HARRY J. GREENE. Phlebitis in obstetrics and gynecology.
 SAMUEL A. WOLFE and IRVIN NEIGUS. Studies with gonadogen.
 Dry clinic: Urology—10.
 ABRAHAM D. SEGAL. Diagnosis and treatment of solitary cyst of the kidney by aspiration and injection.
 LOUIS H. BARETZ. Treatment of hydrocele by sclerosing agent.
 ZACHARY R. COTTLER and SAMUEL PARNASS. Periostitis and ostitis pubis complicating urological procedures.
 PERRY KATZEN. Obstructive uropathy in children.
 ISADORE KIMMEL and PAUL W. ASCHNER. Serum acid phosphatase in the diagnosis and management of carcinoma of the prostate.

KINGS COUNTY HOSPITAL

Monday

- JOSEPH TENOPYR—10. Ward walks and demonstration of fractures.

Tuesday

- GEORGE A. DIXON—9. Operative clinic including gastrectomy, etc.
 JOHN F. RAYCROFT—2. Discussion of fractures of the upper humerus illustrated with lantern slides and follow-up cases.

Wednesday

- JOSEPH TENOPYR—10. Demonstration of fractures and apparatus; visit to the occupational therapy department.
 OTOKAR TENOPYR. Treatment of fractured patella by complete removal of patella and suture of ligaments of knee.

KINGS COUNTY HOSPITAL—DEPARTMENT OF NEUROLOGICAL SURGERY

- M. FRANK TURNER. Glossopharyngeal neuralgia associated with cardiac arrest.
 JEFFERSON BROWDER. Treatment of postherpetic pain by excision of the implicated skin.
 RICHARD GRIMES. Modification of congenital spasticity by selected dorsal root rhizotomy.
 EVERETT W. CORRADINI. Diagnostic use of combined angiography and ventriculography.
 ARTHUR BACON. Bilateral aneurisms—one on each common carotid artery.
 JOHN P. GALLAGHER. Dorsal cordotomy for painful phantom limb.

(Time to be announced)

LONG ISLAND COLLEGE OF MEDICINE
(Kings County Hospital)*Wednesday*

- Dry clinic: Gastric surgery, late results. Biliary surgery, late results. Rectal surgery, late results.

Thursday

- Dry clinic: Early results following sympathectomy for peripheral vascular disease. The value of open bone surgery in early restoration of the patient.

LONG ISLAND COLLEGE HOSPITAL

Tuesday

- Obstetrics and gynecology—a.m.
 GEORGE M. PHILAN. Surgical management of Bartholin cysts.
 MERVYN V. ARMSTRONG. Addison's disease complicated by pregnancy.
 WILLIAM T. DAILY. Syphilis and pregnancy.
 SAMUEL A. WOLFE. Endometrial study after x-ray therapy for polyhormonal amenorrhea.
 SANFORD KAMINSTER. Ectopic kidney as a complication of labor.
 JOSEPH CRESI. Heart disease and pregnancy.
 Urology—p.m.
 FEDOR SINGER and staff. Operations, demonstrations, cases, end-results.

Wednesday

- General surgery—a.m.
 EMIL GOETSCH and staff. Operative program, thyroidectomy and other procedures.
 EMIL GOETSCH, ARTHUR GOETSCH, ALBERT J. RITZMANN. Symposium on thyroid disorders.
 GAETANO DEYOANNA. Curare in abdominal surgery.
 HAROLD LAROE. Complications of Meckel's diverticulum.

SURGERY, GYNECOLOGY AND OBSTETRICS

Thursday
 Obstetrics and gynecology—*a.m.*
 MORRIS GLASS. Postmenopausal bleeding.
 ALEXANDER ROSENTHAL. Iontophoresis in the treatment of chronic pelvic infection.
 ARTHUR S. MACGREGOR. Conservative management of placenta previa.
 CARL TAFFTEN. Conservative management of the vagina.
 CHARLES A. WEYMULLER. Measures for the protection of newborn infants.
 HARVEY B. MATTHEWS. Chronic endocervicitis, pathology, symptoms and treatment.
 VINCENT P. MAZZOLA. Sodium-pentothal in major obstetric and gynecologic surgery.

Friday
 Fractures and other traumas—*a.m.*
 S. POTTER BARTLEY and HAROLD LAROE. Surgery of trauma, demonstrations, cases, end-results.
 General surgery—*a.m.*
 PAUL ANSRO. Modern trends in anesthesia.

METHODIST HOSPITAL

Monday
 Operative and dry clinic—*a.*
 CHARLES A. ANDERSON, EINAR A. SUNDE and staff.
 Otolaryngology.
 JOHN A. FORD. Plastic surgery.

Tuesday
 Operative clinic—*a.*
 HAROLD K. BELL, SEYMOUR G. CLARK and staff. General surgery.
 HENRY P. LANGE and staff. Orthopedic surgery.
 DRY CLINIC—*a.*
 HENRY F. GRAHAM, moderator. Symposium on gastric surgery.

Wednesday
 Operative clinic—*a.*
 PIERRE A. RENAUD, JOHN A. TIMM and staff. General surgery.
 HOWARD T. LANGWORTHY and staff. Genitourinary surgery.
 DRY CLINIC—*a.*
 ARTHUR H. BOGART, moderator. General surgery and specialties.

Thursday
 Operative clinic: Obstetrics and gynecology—*a.*
 GEORGE H. DAVIS, HARRY W. MAYES, HENRY P.

HAGSTRÖM, HENRY S. ACKEN, STANLEY C. HALL and staff.
Friday
 Tumor clinic (late results)—*a.*
 Hospital staff. PIERRE A. RENAUD, moderator.

ST. JOHN'S HOSPITAL

Monday
 General surgery—*a.*
 Operative clinic. Ward rounds.
 Plastic surgery—*a.*
 Operative clinic. End-results in cleft palate. Demonstration of cases.

Tuesday
 Gastrointestinal surgery—*a.*
 Operative clinic. Ward rounds on gastro-intestinal ca. Conference in x-ray department. Conference in the laboratory. End-results in duodenal ulcer.
 Thoracic surgery—*a.*
 Operative clinic. Preoperative and postoperative care of bronchiectasis.
 Ward rounds—dry clinic. Discussion: Surgical treatment of bronchiectasis.

Wednesday
 Goiter surgery—*a.*
 Operative clinic. Preoperative and postoperative care. The abuse of thiouracil in hyperthyroidism. Ward rounds. End-results in toxic goiter.
 Urology—*a.*
 Operative clinic. End results. Heminephrectomy for horse shoe kidney. Cancer of ureter—end results. End-results in cancer of the bladder.

Thursday
 Fractures and other traumas—*a.*
 Operative clinic. Visit to fracture clinic. X-ray demonstrations of interesting fractures. End results in fractures of the femur ward rounds.
 Gynecology—*a.*
 Operative clinic. Demonstration of gross specimens of ovarian tumors. End-results in tumors of the ovary.

Friday
 Surgery of the hand—*a.*
 Operative clinic. Visit to the hand clinic. Motion pictures of operations for lesions of the hand—end results. Round table discussion.
 Ear, nose and throat surgery—*a.*
 Operative clinic. Endoscopic procedures. Conference in x-ray department. General discussion.

about one-half inch throughout the length of this layer. This, as performed by the writer since 1942, is almost exactly the method of placing the first layer of sutures advocated by Skinner and Duncan. The anatomical advantages of closing the internal ring deep to the cord and transferring the latter to the upper angle seem obvious.

6. The free margin of the sheath of the internal oblique muscle is then re-attached to the transversus aponeurosis adjacent to the inguinal ligament with cotton sutures, starting at the superior angle of the wound, and proceeding inferiorly only as far as one can go without tension. This brings the free margin of the internal oblique muscle well below the level of the newly reconstituted internal ring in every case.

7. The medial and lateral leaves of the external oblique aponeurosis have usually been stretched somewhat by a hernia of any size, permitting imbrication across the lower portion of the previous suture line without tension, deep to the cord. The medial leaf is usually brought across first, the lowest suture again being placed through all structures down to the pubis. These leaves are imbricated under only the slightest tension with cotton sutures as far superiorly as possible, the cord again being retracted superiorly and laterally in an oblique plane through all fascial layers. The imbricated external oblique aponeurosis is sutured to the underlying deep layer in the lower inch of the closure.

8. The *transfer* of the cord to the fat, with obliteration of the inguinal canal, has been described. The writer has tried to persuade his colleagues and his students for years of the incorrectness of the usual phrase "transplant" of the cord, and will persist in an apparently hopeless effort at accurate descriptive terminology. It is, perhaps, of interest that all the steps in the "complete" (full-length) revision, or plastic repair, of the wall, with the exception of the avoidance of the inguinal ligament in closure and the routine opening of the peritoneum in monolocular direct hernia, were part of the routine radical operation for inguinal hernia as performed by Willard Bartlett, Sr., in 1928 when the writer joined his father in the private practice of surgery.

A case can be made for the "limited" operation in which the transperitoneal exploration reveals only moderate dilatation of the internal ring (to less than half the total length of the posterior wall) and a firm lower portion. The writer sees no advantage to be gained by obliteration of the inguinal canal in such instances. High division and suture of the sac, excision of the upper portion of the cremaster muscle as described, and approximation of the margins of the internal ring behind the cord deal thoroughly with the situation at this simple stage. The mobilized internal oblique is replaced and closure in anatomical layers completes the operation. This procedure should supplant the Ferguson operation entirely, as it avoids damage to the internal oblique muscle, accurately diminishes the size of the internal ring and thereby restores the posterior wall at its point of weakness under these circumstances, which the Ferguson does not do. On the basis of his experiences in the service, and of the anatomical data referred to, the writer would expect this "limited" plastic repair to be the procedure of choice in nearly 50 per cent of adult males under 30 years of age, with far less frequency in patients above that age and in practically all children.

SUMMARY

There is a wide difference between the traditional conception of inguinal hernia and that which is currently postulated on the basis of recent clinical and anatomical observation. The resemblance is slight between Bassini's ideal of "the rebuilding of the hernial canal, as this exists under physiological conditions, that is, a canal with two openings, an abdominal and a subcutaneous, further, with two walls, a front and a back, through the middle of which the spermatic cord would run obliquely"—and our adoption of all available means to obliterate the canal. We know that we cannot bring the transversus and the internal oblique muscles to the inguinal ligament and make them stay there and we suspect that we damage them in making the attempt. We are confident that the margins of the transversus aponeurosis and of the transversalis fascia cannot be accurately de-

head, the surgeon has the option of resorting to the Gill procedure. He has recommended the employment of arthrodesis of the hip joint in certain individuals for ununited fractures of the femoral neck in which any reconstruction procedure may be destined to failure. Such an arthrodesed hip joint achieves a stable, painless, weight-bearing member, even though it is stiff, and may be preferable in some individuals in whom stability is a very important requisite for recovery.

In considering the methods of treatment of ununited fractures of the neck of the femur in patients who have a viable head, the surgeon has the option of employing one of the operative procedures designed to achieve anatomical and physiological restoration, or of employing the reconstruction procedure. Various types of osteotomies have been widely employed with excellent results. The Lorenz and Schanz osteotomies have been modified until these procedures have become greatly improved and simplified. Hass described the application of the Lorenz bifurcation operation, particularly as it pertains to ununited fractures of the femoral neck. The object of the original Lorenz and Schanz osteotomies was the attempt to overcome lateral stress of the fractured femoral neck on the head, so that the distal portion of the neck would assume a position inferior to the head, instead of lateral to it, thereby eliminating the shearing force of the neck and trochanter on the head. In the original operation, it was considered that a good result had been obtained merely when this shearing force was overcome and the head was resting directly on the ununited distal portion of the neck. These operative procedures entailed considerable sacrifice of length and, in spite of the fact that there was greater stability in the hip joint, some of these individuals continued to have pain and restriction of movement with resultant functional impairment and disability.

There have been many modifications of the osteotomy, but the McMurray type of high oblique osteotomy has been by far the greatest advance in the treatment of ununited fractures of the femoral neck. When this type of osteotomy was performed, it was found that not only had the operation completely overcome the shearing force of the neck on the head, but also that union of the osteotomy surfaces, and, in a great number of instances, between the ununited head and neck, had been achieved. As a matter of fact, a great number of cases have been reported in which union has occurred following osteotomy even as late as 2 years after the occurrence of the original

fracture. As a consequence, there was also less sacrifice of length of the leg than in the Lorenz and Schanz procedures.

Because of these improvements, the criteria for good end results have been completely revised. A good end result now implies complete correction of the shearing force of the neck on the ununited head, with union of fragments, less shortening, a remarkably increased range of motion, very little pain or discomfort, and a surprising restoration of function. The reports from many sources indicated a marked reduction in the mortality, no postoperative shock, almost no postoperative infection, and a minimal period of disability. As a consequence, the percentage of good end results from the McMurray type of osteotomy has been reported to have increased over that of the many other procedures which had been advocated.

Since the osteotomies have all been considered more or less "blind" or subcutaneous operations, difficulty was encountered in gauging the proper level of the osteotomy. The high oblique osteotomy has been preferable because it was designed to impinge the neck directly under the head so that the weight-bearing alignment would follow directly downward from the head into the shaft, completely shunting off the angle of the neck of the femur. The object of the high osteotomy, as reported by McMurray, has been to attain better apposition of the ununited fractured surfaces, and it is believed that the attachment of the muscles to the lesser trochanter greatly assisted in drawing the distal fragment medially, and maintaining this apposition. It is therefore advisable, if possible, to direct the osteotomy above the level of the trochanter, as advocated by McMurray. In spite of careful planning of the site for the osteotomy, some osteotomies have been done either too high or too low, resulting in failure of this operation. The writer suggested the insertion of the Steinman pin or drill at the proposed site of the osteotomy, and checking the hip roentgenographically before the osteotomy was finally performed.

Leadbetter's recent cervical-axial operation for ununited fractures of the femoral neck is unquestionably a great advance in the treatment of this condition. This operation completely eliminates the "blind" phase of the osteotomy by presenting a very simple exposure over the site of the ununited femoral neck, and permits performance of the osteotomy directly through the desired site. By visualizing the area one can correctly gauge the level for the osteotomy, thus achieving even less sacrifice of length than in other procedures. At the same time, the surgeon more easily implants the distal fragment under the

head and neck, and thus observes the exact position that has been accomplished.

In his consideration of the osteotomy, Leadbetter has very succinctly catalogued six criteria for an ideal osteotomy, namely:

1. Preservation of the articulation of the head and the acetabulum.
2. Establishment of a normal acetabular thrust.
3. Creation of positive pressure by a true valgus.
4. Allowance for contact of cancellous bone surfaces.
5. Preservation of adequate circulation.
6. Production of minimal shortening.

The Brackett operation also was designed to implant the remnant of the neck or trochanter into the femoral head by visualization through operative exposure, and Ghormley recently reported a series of patients on whom this reconstruction procedure was employed with good results. Some surgeons consider the Brackett operation somewhat similar to the Leadbetter procedure. The ununited fracture is exposed by open operation and after the greater trochanter has been divided by osteotomy, the remnant of the neck or trochanter is implanted directly into the ununited fractured head which has been freshened and slightly gouged out.

Blount has advocated the use of a blade-plate as a means of internal fixation following femoral osteotomies, for the purpose of eliminating the necessity of the application of the hip spica cast.

He considers the hip spica a distinct detriment to the patient's welfare because of the enforced period of recumbency, and the application of a blade permits more rapid convalescence and earlier weight bearing and locomotion.

DISCUSSION

The selection of the proper type of operative procedure for the relief of ununited fractures of the neck of the femur is dependent upon many factors, and the state of the ununited femoral head is extremely vital in its selection. Whether the head is viable or not is, of course, of first consideration in the selection of the proper procedure. If the head has undergone aseptic necrosis or secondary arthritic change, one must immediately eliminate all types of operations designed to restore anatomical and physiological function. Any type of osteotomy is also contraindicated. The choice of operative procedure lies between arthrodesis of the hip joint, as recommended by Gill, or the Whitman reconstruction operation in which a portion of the trochanter and neck is implanted into the acetabulum after the removal of the necrotic head, with the trochanter transplanted downward, or the Colonna operation, in which the greater trochanter is directly implanted into the acetabulum after the removal of the head.

In those instances in which the original fracture of the femoral neck has occurred far medially at the junction of the head and the neck, leaving

Fig. 2-A, Roentgenogram taken January 16, 1940 showing fracture of neck of femur with coxa vara of 6 weeks' duration. B, Roentgenogram taken April 6, 1940, of high oblique osteotomy, showing coxa vara completely corrected

with lesser trochanter directly under head. C, Roentgenogram taken August 17, 1940 showing union of osteotomy and femoral neck, head and trochanters in excellent relation to shaft. (Reich, R. S.: *J. Bone Surg.*, 1941, 23:141.)

a small remnant of the head in the acetabulum, even though viable, the various osteotomies may also be contraindicated, because of the lack of adequate purchase of the neck on the remaining head. Failures have frequently resulted from the osteotomies in which these conditions have prevailed. For this reason, such a small remaining head, even though viable, may also be considered additional indication for the Whitman or Colonna operation. A very small remnant of the head may also be considered a contraindication for the dowell bone grafting operation, particularly if it is associated with a short neck, as the operation may result in a very marked restriction of motion of the hip joint, even though the bone grafting operation may be successful.

Fortunately, by far the largest proportion of instances of ununited fractures of the femoral neck are those in which the head is viable, and on which there is a small portion of the neck attached. In this group, the selection lies between the dowell bone grafting operation designed to restore anatomical and physiological relation, and the osteotomy employing either the original Lorenz or Schanz procedures, or the McMurray type of operation with the further improvement as recommended by Leadbetter. All of these procedures require immobilization of the operated hip by means of the application of a hip spica.

Despite the fact that a great many very satisfactory results have been reported following the

employment of the high osteotomy, there have been a number of instances in which the operation has been unsuccessful. It may be well to review the causes of these failures:

Improper selection of the level for the osteotomy
If the level has been selected too high, it is difficult to maintain the distal osteotomy fragment under the head and proximal portion of the osteotomy. In some instances the osteotomy has slipped. If the osteotomy has been too low, difficulty may be encountered in maintaining the distal portion of the osteotomy under the head, and union between the head and the distal portion of the osteotomy may not occur. Both these difficulties may well be obviated by the employment of the Leadbetter cervical-axial operation.

Loss of joint motion. This may be due to the fact that the ununited head may not have been viable, or to the fact that there may have been early aseptic necrosis, or that osteoarthritis may not have been detected. In these instances restriction of motion may result. The osteotomy appears to stimulate revascularization of the hip joint proper, and osteosynthesis (Wilson).

It has been the writer's experience that in some patients on whom an osteotomy had been performed, and the ununited head had shown questionable viability, later roentgenograms showed definite improvement in the bone density of the femoral head, with consequent union, probably the result of revascularization.

Fig. 3. A, An ununited fracture of the femoral neck of 14 months' duration in a patient 65 years of age. B, Four weeks after operation. Note the high level of the osteotomy, the valgus position with positive thrust, and the moder-

ate degree of abduction. C, Ten weeks after osteotomy the firm and stable position is noteworthy. The patient is bearing weight at this time. (Leadbetter, G. W., *J. Bone Surg.*, 1944, 26: 713.)

The fibrous union between the surfaces of the ununited fracture has become so dense that the fragments have not become separated, thus preventing direct contact between the distal osteotomy surface and the proximal fragment of the neck and head. This difficulty in separating the fragments has been clearly demonstrated in the cervicoaxial procedure of Leadbetter, and must be considered an extremely important advantage in the open operation. It has been proved that the earlier the osteotomy has been performed after the nonunion has been established, the better the end results have been, because of less dense fibrous union. There is another distinct advantage in performing the osteotomy early, and that is that less shortening may have resulted, so that the osteotomy may be done at a higher level.

Blount lays considerable emphasis on the fact that the application of a hip spica cast constitutes a direct hardship to the patient, and recommends fixation of the osteotomized fragments by means of a blade-plate. He also calls attention to the fact that there is resultant stiffness of joints, particularly of the knee joint, following immobilization in a hip spica cast. In his opinion, it is important to fix the osteotomized fragments by

internal fixation in order to prevent slipping, which he states may occur even in a properly applied hip spica. The high oblique osteotomy is the procedure of choice of most orthopedic surgeons; consequently this operation has been performed on a great many individuals, and the hip spica has not been in any way detrimental to the patient's welfare. The operation is so designed that the hip spica does not cause any strain upon the knee joint capsule. In addition, this cast rarely remains applied for longer than a 6 weeks' period, and in many instances only 4 weeks, so that there is very little opportunity for any ill effects to result from its application, either as a debilitating factor, or as a cause of joint stiffness, particularly to the knee joint.

It is needless to say that the application of any type of internal fixation following an osteotomy entails extensive operative technique which cannot help but be shocking to those unfortunate individuals who, in most instances, are not only of advanced age, but have become debilitated because of a long period of disability.

We must not lose sight of the fact that this type of operation, in addition to its very complicated operative technique, involves the use of

Fig. 4 A and B, Anteroposterior and lateral views of right hip show an ununited fracture of the femoral neck of

1 year's duration. The Trendelenburg sign was positive on the right and negative on the left.

a blade-plate, which necessitates, in addition, the insertion of a number of bone screws. All these obviously constitute the application of a number of foreign bodies which are potentially productive of postoperative infection. On the other hand, the high oblique osteotomy is a simple procedure which can be performed in a very short time, with minimal tissue trauma and consequent hemorrhage, and there is no ensuing shock even after the application of the hip spica. The same may be said of the Leadbetter operation, which also can be carried out rapidly, with minimal tissue trauma and hemorrhage, and no shock.

In the opinion of the writer, there is another contraindication to any type of internal fixation following an osteotomy. It has been frequently observed that the distal portion of the osteotomy is apt to wander farther inward under the head and proximal portion of the neck a few days after the osteotomy has been performed, during the process of absorption of the osteotomy surfaces preliminary to osteogenesis. This is due to the pull of the muscle attachments to the lesser trochanter, and constitutes a decided advantage in that the distal portion of the osteotomy rests further under the head and thereby contributes to a more adequate weight-bearing alignment. This obviously cannot occur when the fragments have been locked by internal fixation. Blount

has stated that internal fixation is considered necessary to maintain the position of the fragments of the femur following osteotomy, and thereby prevent slipping. This might well be true for any type of low osteotomy, particularly the Schanz osteotomy, but does not prevail in any high type of osteotomy. It is extremely rare that the osteotomy fragments alter their position after the distal portion has been adequately aligned under the head, and if there is malalignment of the fragments, this condition must be ascribed to faulty operative technique. In the writer's opinion, the only contraindication to a hip spica following an osteotomy would be in the case of an individual with an arthritic knee joint, with impending ankylosis, or in whom such ankylosis may result from prolonged immobilization, in which instance a blade-plate may be indicated.

In comparing the high with the low osteotomy, it is observed that some surgeons prefer the low Schanz osteotomy to the high. The writer believes there are definite disadvantages in the use of the low osteotomy as recommended by Schanz:

1. There is necessarily a greater sacrifice of length because it entails the excision of a wedge-shaped portion of the femur.
2. It requires a greater angle and consequently a longer lever arm both above and below the angle. These features contribute to additional

Fig. 4 C and D, Anteroposterior and lateral views of right hip 1 year after osteotomy with blade-plate fixation. (In recent cases an additional screw has been used in the proximal fragment.) The patient began to walk with crutches 8 days after the operation, and left the hospital on the twelfth day. Full weight bearing was possible in 8 weeks. He returned to farm work in 14 weeks. The Trendelenburg sign was negative. (Blount, W. P. *J. Bone Surg.*, 1943, 25: 319.)

shortening. Because of the location of the osteotomy it is more difficult to maintain the osteotomy fragments in position, and for this reason some form of internal fixation is essential.

3. Because of the fact that there is a greater angle at the site of the osteotomy, greater obliquity in the weight-bearing line of the lower extremity, with a greater incidence of knock-knee deformity, must ensue. The knock-knee deformity also occurs in some instances in which the high osteotomy has been performed, but not as frequently as in the low osteotomy. In some instances supracondylar osteotomies have had to be performed secondarily in order to correct the knock-knee deformity.

SUMMARY

All individuals with ununited fracture of the neck of the femur may be divided into two groups, and the choice of operative procedure depends upon the group in which the patient may be classified: (1) those patients in whom the ununited head has undergone aseptic necrosis or secondary arthritis; and (2) those patients in whom the head is viable and in whom there is a remnant of the neck attached to the head.

For the first group, the surgeon has a choice of performing an arthrodesis of the hip joint, as recommended by Gill, or of performing the reconstruction operation, as described by Whitman and Colonna. For the second group, in which the head is viable, the condition may be relieved by the Albee bone grafting operation, or a modification of this procedure by the insertion of internal fixation in addition to the bone graft. The alternative is to perform one of the various types of osteotomies that have been recommended. The high oblique osteotomy has proved to be by far the most satisfactory and the simplest procedure to carry out; and the Leadbetter cervical-axial osteotomy has greatly simplified the operative procedure and has completely eliminated the so-called "blindness" in the selection of the site of the osteotomy. The blade-plate fixation of the osteotomy fragments entails an extensive operative procedure no less shocking and difficult than the bone grafting type of correction. The application of the hip spica cast following an osteotomy results in no difficulties to the patient, as it remains applied for a maximum of 6 weeks and the patient may be moved the day following the operation. It may consti-

tute a contraindication in a patient with an arthritic knee, in which instance the application of internal fixation, such as a blade-plate, may be preferable.

The criterion for a good end result has been materially altered since the high oblique osteotomy. Whereas, in the early cases, stable weight-bearing of the hip was considered a good result, now the objective is healing of the nonunion together with the osteotomy surfaces, and painless adequate joint motion, with a minimum of shortening.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Dandy, W. E.: Arteriovenous Aneurysms of the Scalp and Face. *Arch. Surg.*, 1946, 52: 1.

Although between 200 and 300 aneurysms of the scalp and face have been reported, they are very rare in the experience of the individual surgeon. Those occurring in the scalp and face are more common than those arising elsewhere in the integument. Nine cases are reported here, including 1 from the clinic of Blalock. Six of the 9 cases reported belong to a rare group in which the primary arteriovenous aneurysm was in the dura and the extracranial aneurysm arose from numerous perforations of the bone from branches of the dural aneurysm. Five of these cases also presented intracerebral aneurysms, as was demonstrated by a right homonymous hemianopsia; the intracerebral aneurysm, in turn, was connected with the middle meningeal arteries, and these were regarded as the point of origin.

The 9 cases were operated on and full case reports are appended with diagrams and illustrations to aid in the understanding of the underlying mechanisms. Only 1 case was considered to be of traumatic origin, the others being regarded as congenital. It was clearly shown in 7 cases that the arteriovenous aneurysm of the scalp derived its arterial component from the middle meningeal artery coming through the skull. These cases can be divided into two groups: (1) in which the preformed genuine arteries come through the skull and enter a primary congenital angiomatous mass, and (2) in which numerous thin-walled vessels penetrate the skull and form an arteriovenous bed without a primary angiomatous mass in the scalp. Both types are likely to derive a bilateral arterial supply from the middle meningeal arteries. In all but 2 cases the aneurysm was in the parieto-occipital region. In 5 cases the right and left middle meningeal arteries were about equally enlarged, and the hemianopsic defect was always unilateral. This was taken to indicate that the intracerebral aneurysm was unilateral as the intracerebral lesion was partly exposed at operation in only 3 cases. The size of the extracranial aneurysm was believed to be inversely proportional to the intracranial.

Headaches, dizziness, noises in the head, and a pulsating mass were the reasons for which the patients presented themselves for medical attention. Only 4 had convulsions but these do not necessarily signify intracranial extension of the aneurysm because other congenital lesions may be present and may be contributory.

The author then summarizes the various methods of surgical treatment. It is said to be doubtful whether ligation of any of the large arteries in the

neck can produce anything but temporary improvement. The exception is, of course, in the aneurysms of the eyelid and face in which ligation of the internal and external carotid arteries on the affected side is indicated. Ligation of the scalp vessels is useless. The intracerebral aneurysm cannot be adequately managed. It is recommended that one or both middle meningeal arteries be tied and that the scalp lesion be attacked directly. Bone flap operations are absolutely contraindicated on account of profuse bleeding from enormous vessels. Removal of bone can be accomplished only piece by piece with the bone biters and the immediate application of large quantities of bone wax. Most of the patients were very much relieved following extirpation. There were no deaths.

This comprehensive article is one of the last of Dandy's voluminous and far reaching contributions to the surgical literature before his untimely recent death.

ARNOLD VAN BRUGGEN, M.D.

Dingman, R. O.: Ankylosis of the Temporomandibular Joint. *Am. J. Orthodont.*, 1946, 52: 120.

The author presents a résumé of the incidence, effects, and pathology of temporomandibular joint ankylosis. The disease itself is quite amenable to surgery, but if it is allowed to go untreated, it interferes with mastication and nutrition, prevents proper oral hygiene, and precludes the possibility of proper dental care. In children it leads to maldevelopment of the mandible with attendant speech defects. Occasionally such disease will have serious consequences in that an acute surgical disease of the mouth or esophagus will be comparatively inaccessible.

The disease is more common in males. It occurs at any age, although usually in a younger individual and more commonly on only one side. Pathologically, true temporomandibular ankylosis is an intra-articular disease which commonly follows trauma or infection. This disease may also be simulated by a false ankylosis due perhaps to scar contractures around the region of the joint, bony tumor, or depressed zygomatic fracture. The pathology is usually much the same, notwithstanding the different etiology. It consists essentially of destruction of the articular surfaces, fibrosis of the capsule and ligaments with subsequent ossification, obliteration of the joint cavity, and joint fixation. It may be due to congenital causes, which in the author's experience were very rare, or mechanical causes, which include fractures, dislocations, chronic osteoarthritis, and suppurative processes in and around the joint (the ear, parotid gland, skull, or mandible); or it may be the result of a metastatic infection. The diagnosis is

generally made on the basis of a long standing history of restricted ability to open the mouth, usually dating from some injury or infection. If the disease starts in youth, generally there is maldevelopment of the lower jaw with a flatness of the face of the uninvolved side. There is a shift of the mandible to the involved side on opening the mouth and some crepitation upon palpation over the joint.

The author suggests anteroposterior and semilateral stereoscopic x-ray studies. In the treatment of these cases surgery is so uniformly successful that it should be resorted to in all cases.

Dilators, exercisers, or instruments for forcible opening are either ineffective or useless.

The author then presents his operative procedure which he does under local anesthesia whenever possible. He closes the operative wound in layers with drainage. Bilateral operation is usually done in two stages with a 4 to 6 weeks' interim.

He believes that the insertion of any type of foreign material, such as metals, acrylics, and heterografts, is to be condemned and that the operative hematoma will give rise to sufficient fibrous tissue in the affected region.

LOUIS T. BYARS, M.D.

Inclán, A., Jr.: The Use of Haynes' Maxillary Splint in a Case of Grafting of the Mandible. (Uso de la férula de Haynes en un caso de injerto óseo del maxilar inferior). *Cir. ortop. traumat.*, Habana, 1945, 12: 132.

Since March, 1944 external splinting has been used in the orthopedic service of the author. The Zimmer splint was first used, but, later on, the Haynes splints were employed. At present both types are used and combined according to the requirements of each case. In the case here presented, the Haynes splint was used in the reconstruction operation of the inferior maxilla by bone grafting; the loss of substance was due to a large surgical exeresis of the portion between the symphysis and the angle, which was done elsewhere because of a tumor of the lower jaw. Up to the present time there has been no evidence of recurrence or metastasis.

The Haynes splint is made of screws that are introduced in the bones and connecting bars which fix the screws and permit a high degree of adaptation in various positions.

In the present case it was decided to employ a bone graft 8 cm. long that had been taken from the posterior segment of the 10th rib. Two screws of the splint were introduced into the ascending ramus, 2 in the costal graft, and 2 in the body of the maxilla on the opposite side; all the elements were fixed by means of their connecting bars. No internal fixation, whatsoever, was used and immobilization was maintained for 15 weeks; at the end of this time fusion was present.

The Haynes splint has the advantage of permitting the mastication of soft foods and oral hygiene, both of which are impossible when wires are used to fix the inferior maxilla to the superior one. Furthermore, when the bone defect is of such extent

as the one presented, the Haynes splint permits a degree of fixation which cannot be obtained and maintained by the ordinary methods of fixation.

The clinical history of the patient, corresponding roentgenograms, and details of the operation are given. Fixation by wires on the uninvolved side, to insure good occlusion, was done before the operation. A week after the operation the occlusion wires were removed to permit the mastication of soft foods. Fifteen weeks postoperatively the splint was removed and the graft was firmly fused. The patient has been seen recently (165 days postoperatively); he is in good condition and ready for a dental prosthesis.

F. F. Remy, M.D.

EYE

Stone, L. S.: Return of Vision in Transplanted Adult Salamander Eyes after 7 Days of Refrigeration. *Arch. Ophthalm.*, 1946, 35: 135.

The experimental results of transplanting 70 enucleated, refrigerated salamander eyes are reported. Grafts kept at freezing temperatures eventually degenerated; those kept at 8°C. degenerated if refrigerated longer than 2 days; and those kept at from 4 to 6°C. were successfully transplanted, with functional return of vision demonstrable after refrigeration for 7 days. The corneal tissue was noted to be among the best preserved of the transplanted tissues.

HUNTER H. ROMAINE, M.D.

Lyfe, T. K., Cross, A. G., Simpson, J. F., and Fraser, G. A.: Dacryocystorhinostomy. *Brit. J. Ophthalm.*, 1946, 30: 102.

Fifty-six cases of dacryocystorhinostomy are reported, including 24 post-traumatic cases. The classical type of surgical technique was followed, being modified, however, to include those cases in which an incomplete excision of the lacrimal sac had previously been done. Contraindications were listed as follows:

- (a) Previous complete excision of the lacrimal sac. (N.B. This can usually be determined only at operation.)
- (b) Destruction of the inferior canaliculus.
- (c) Obstruction of the nasolacrimal duct, due to tuberculosis, malignant neoplasm, and to most of the other causes.
- (d) Atrophic rhinitis.

Of the cases which were followed up, 78 per cent were completely symptom free, 13 per cent were much improved, and 9 per cent showed no improvement.

HUNTER H. ROMAINE, M.D.

Struble, G. G., and Croll, L. J.: Removal of Magnetic Foreign Bodies. *Am. J. Ophthalm.*, 1946, 30: 151.

In the removal of magnetic foreign bodies from the eye by the posterior route the authors emphasize the following technical points:

1. Exact localization of the foreign body, especially when it is imbedded in the choroid or retina.

After preliminary x-ray localization a lead marker is attached to the sclera at the point the foreign body is believed to lie and portable x-ray apparatus is used to confirm the position before an incision is made. This somewhat prolongs the operation but the very exact localization thus possible prevents a lateral drag on the choroid or retina, keeps bleeding at a minimum, and reduces the postoperative reaction.

2. Fixation of the globe by scleral silk sutures, one on either side of the incision results in complete control of the operative area, permits traction on the sclera while the incision is made in the sclera, and helps to prevent penetration of the choroid.

3. The sclera is divided layer by layer with a cataract knife and after it is penetrated for about four-fifths of its thickness a catgut suture is placed through each lip for eventual closure of the scleral incision. The incision is then completed down to the uvea without penetration of the latter. It should be about 6 mm. in length.

4. The hand magnet is placed in contact with the uvea and the foreign body removed through it. Foreign bodies less than 0.5 mm. in size may require that a small nick be made in the uvea to facilitate delivery. Larger foreign bodies will pass through the uvea without causing a significant tear.

5. The scleral incision is closed with the catgut sutures previously placed in the sclera.

6. A diathermic barrage is placed around the incision but not penetrating the sclera. Surface coagulation may be substituted.

Experimental studies were made on fresh hogs' eyes to determine the pull of the magnet on foreign bodies placed in the vitreous, and it was found that a pars plana approach for these was satisfactory when the foreign body lay within the "certain" or "critical" zone for the size and weight of the foreign body. Diagrams are submitted for various sized fragments and these are of considerable interest.

WILLIAM A. MANN, M. D.

Friedenwald, J. S., Hughes, W. F. Jr., and Herrmann, H.: Acid Burns of the Eye. *Arch. Ophthalm.*, 1946, 35: 98.

The authors state that acid burns of the eye are more benign than alkali burns. Mild burns recover regardless of the type of treatment; severe burns caused by high concentrations leave opacities, perforation, or symblepharon. Corneal epithelium is highly protective against acids and it has a buffering capacity for solutions below pH 4.0. Isotonic solutions of hydrochloric acid, of 0.005 normal concentration (pH 2.5) or stronger, or exposure to isotonic solutions of citrate-phosphate-borate buffer at pH 4.5 or below, produced ocular lesions.

The severity of the lesion in the cornea by acids is related directly to the protein affinity of the anion. Anions, which have a high protein affinity and protein precipitating ability, produce corneal lesions at a higher pH than anions with low protein affinity, but these large anions (with high protein precipitating

ability) penetrate poorly through the corneal epithelium and diffuse poorly into the stroma. Such precipitation and denaturation of the proteins of the cornea account for the clinical and pathological characteristics of acid burns of the cornea.

JOSHUA ZUCKERMAN, M. D.

Cutler, N. L.: A Basket Type Implant for Use after Enucleation. *Arch. Ophthalm.*, 1946, 35: 71.

A basket type of lucite was inserted into Tenon's capsule in 50 cases of enucleation of the eyeball.

It is the accepted opinion that a more adequately filled socket and a better functioning stump are obtained with any type of implant than without one. The basket implant was devised to provide the socket with a better grip on the prosthesis which has a stud projecting posteriorly, to grip the stump.

The lucite basket, which is fenestrated to allow for the invasion of tissue, measures 11 by 15 mm. There are three holes in the bottom, two of which are for sutures. A lucite button, 5 by 8 mm., with 0.8 mm. holes, is used to tie the sutures through. Three double armed sutures of different colors are used to permit ready identification: black O nylon, blue OO dermal, and purple coarse dermal sutures.

After the conjunctiva is dissected from the limbus and to the fornices in all directions, the rectus muscles are isolated and severed from their insertions. The conjunctival opening is enlarged nasally and temporally about 2 mm., to permit passage of the globe. The globe is grasped with fixation forceps at the tendon of the internal rectus muscle, the nerve is cut, and the prolapsed globe is freed from the oblique muscles and removed.

The basket is then placed in Tenon's capsule and sewed into place by sutures through Tenon's capsule and the conjunctiva.

No attention at all is directed to the re-attachment of the muscles.

Mattress sutures, when pulled up, cause a double imbrication, or folding of Tenon's capsule and the conjunctiva. All the sutures are carried through a lucite stud.

In the prosthesis, the stud is adjusted to fit into the depression, and the base around this stud is cut away to allow the edge of the basket to come forward when the socket is turned.

It is believed that this new type of prosthesis permits more instantaneous movement and a wider range of action.

JOSHUA ZUCKERMAN, M. D.

Cassady, J. V.: Uveal Blastomycosis. *Arch. Ophthalm.*, 1946, 35: 84.

The author reports a case of blastomycosis of the uvea. He points out that there are two types of blastomycosis, cutaneous and systemic, and that the systemic type is fatal in 90 per cent of cases.

In differential diagnosis, the following diseases must be excluded: tuberculosis, coccidioidal granuloma, syphilis, sporotrichosis, and bromide or iodine rash. Pathologically, the picture resembles tuberculosis, including the presence of giant cells, but the

double-contoured bodies of blastomycosis are found in sections of the tissue.

A white male, 64 years of age, presented polyarthritides and discoid, discrete, scaly, elevated lesions of the skin, and severe pain in his right eye. There was a yellowish, tuberclelike nodule in the iris, and total posterior synechia.

The Mantoux test was negative in a 1 to 1,000 dilution. Roentgenograms of bones revealed irregular areas of destruction (without reaction of the bone around the lesions) and scattered areas of consolidation in both lungs.

Histological examination revealed a dense, opaque lesion of the ciliary body and the filtration angle, exudate in the anterior chamber, anterior and posterior synechia, and atrophy of the iris. Tubercles were seen in the deep corneal lamellae and around the canal of Schlemm. Double-contoured bodies were present throughout the mass and in the giant cells. The pathological diagnosis was blastomycotic iridocyclitis, cataract, and secondary glaucoma.

From this case of endogenous blastomycosis (Gilchrist's disease), and from other cases reported in the literature, Cassady concludes that metastatic uveitis associated with systemic blastomycosis is not rare. He suggests that if the eye is involved during the course of a fungus infection, the plasmodial intraocular fluid should be withdrawn for cytologic examination and culture.

JOSHUA ZUCKERMAN, M. D.

Mann, I.: The Intraocular Use of Penicillin. *Brit. J. Ophthalmol.*, 1946, 30: 134.

The study of the effect of injecting solutions of penicillin (0.15 c.c. of a solution containing from 2,000 to 10,000 units per cubic centimeter) into the anterior chamber of the rabbit's eye yielded some interesting results. The pH of the solutions was 6.5 and all of these solutions were made up in normal saline solution. Almost immediately a coagulum formed on the surface of the iris, which began to shrink in about an hour and tended to disappear in about 4 hours. Corneal edema, conjunctival injection, and cells in the aqueous were noted. Most of this reactive aseptic anterior uveitis cleared up in 3 days, but 1 case did not show recovery for 24 days. It is believed that most of the reaction is due to impurities in the preparation available commercially; but a slight reaction was obtained when a pure sodium penicillinate was used.

In 9 rabbits 1,000 units of penicillin (0.1 c.c.) were injected into the vitreous. This was followed by an immediate localized opacity in the vitreous. From 5 to 7 days after the injection a severe exudative retinochoroiditis ensued. There was retinal and choroidal edema and exudate, edema of the papilla, and pronounced vascular changes with hemorrhage. After the seventh day all eyes but 1 appeared to be blind, with loss of reaction to light. Between the second and third week new vessels appeared from the optic disc and the picture of retinitis proliferans developed. This was combined with complete retinal

and optic atrophy. Subsequently a degenerative iritis and, in some cases, cataract appeared. Histological study of these eyes revealed a complex neuroretinal degeneration followed by fibrosis and accompanied by thickening and fibrosis of the choroid. Further studies were made with practically pure sodium penicillinate. Much less was found in the way of chorioretinal reaction, and all of these eyes showed normal fundi in 3 weeks. Therefore, it appears that the serious results of injecting penicillin into the vitreous of rabbits are due not to the substance itself but to the impurities which are associated with it.

After corroborating the fact that the intravenous injection of penicillin did not result in a high enough concentration in the aqueous to be beneficial in infections of the aqueous or vitreous, a study was made on the persistence of penicillin injected into the aqueous and vitreous of normal and inflamed rabbit eyes. The material was not retained in the aqueous in sufficient strength to be effective more than 6 hours. While it disappears from the vitreous less rapidly, the destructive changes in the eye from injections into the vitreous are so severe that it would seem an unsuitable method. There was no evidence that the inflamed eyes retained the penicillin longer than the normal eyes.

Twenty-nine human eyes with perforating injuries were treated by the intraocular injection of penicillin. They were all eyes which would have been inevitably lost without such treatment. Eleven of the eyes were lost in spite of the penicillin therapy, 9 healed but were blind, 1 eye healed with a cataract, 1 regained 6/36 vision, and 1 had 2/60 vision. Of the remaining eyes, 4 recovered, 1 eye had a malignant melanoma, and 1 was removed because of pain.

It is believed from this experience that intraocular injections of penicillin are justified in severely injured or infected eyes, especially when the infection is confined to the anterior part of the eye and the penicillin does not come in contact with the vitreous.

WILLIAM A. MANN, M.D.

Summers, T. C.: Penicillin and Vitamin C in the Treatment of Hypopyon Ulcer. *Brit. J. Ophthalmol.*, 1946, 30: 129.

Nine cases of hypopyon ulcer treated with penicillin locally and vitamin C are reported in detail.

The author has long been enthusiastic in the use of vitamin C given intravenously in daily doses of 500 mgm. The use of penicillin in these cases has impressed him as being very effective. Two hundred units per cubic centimeter were used and one drop was instilled hourly during the day and every three hours at night. In addition, atropine, heat, diathermy, and vitamin C were employed.

The penicillin is apt to cause local irritation after prolonged use and may have to be discontinued. It is suggested that routine carbolicization of all corneal ulcers is not necessary, but curettage of the ulcer before the instillation of penicillin may be advantageous.

The author has the impression that the combined use of vitamin C and penicillin is more effective than the use of either alone, although no statistical evidence of this is presented.

WILLIAM A. MANN, M.D.

Prendergast, J. J.: Congenital Cataract and Other Anomalies following Rubella in the Mother during Pregnancy; a California Survey. *Arch. Ophth., Chic.*, 1946, 35: 39.

A survey is reported among Californian obstetricians, pediatricians, and ophthalmologists, of congenital defects in infants born to mothers who have had rubella during the first 3 months of pregnancy. It is suggested that transplacental transmission of the virus infection arrests the development of embryological structures in the whole body, and especially in the more important organs such as the eye and the heart, in which organs a high incidence of anomalies is reported. HUNTER H. ROMAINE, M.D.

EAR

Korkis, F. B.: Effect of Blast on the Human Ear. *Brit. M. J.*, 1946, 1: 193.

An outline of an Army otologist's views on the incidence, etiology, and types of blast injuries to the ears is given.

The high percentage of associated cochlear trauma in blast ruptures is stressed.

Infection after rupture occurs in approximately half of the cases, and usually begins within 4 days of the injury.

A half-yearly otological examination of soldiers to determine the presence or absence of blast deafness is indicated.

The prognosis is doubtful and should be guarded. Residual deafness may remain.

Routine audiometry upon demobilization is advocated.

JOHN F. DELPH, M.D.

Lindsay, J. R.: Histological Observations on the Healing of Labyrinthine Fistulas in Monkeys. *Arch. Otolaryng., Chic.*, 1946, 43: 37.

The results which are now available from the first half of this series of fenestration operations on monkeys seem to warrant the following interpretations regarding the regeneration of bone at the fistula:

The fistula in the bony semicircular canal always closes by formation of new bone unless certain measures are carried out.

The regeneration of bone occurs rapidly from the periosteal layer and more slowly from the endosteal surface of the capsule. Complete closure may occur from either or both layers.

Attempts to prevent regeneration of the periosteal bone have resulted as follows:

r. The use of a cutaneous flap reflected from the posterior wall of the external auditory meatus without removal of the annulus tympanicus was not successful. The situation of the fistula in a concavity

tends to prevent close contact with the covering flap throughout the healing period.

2. Thiersch grafts of hair bearing skin were frequently successful in preventing closure for several months, but proved to be unsatisfactory because of occasional degeneration and because of the presence of hair fragments beneath the graft, which stimulated the formation of callus and eventual closure.

3. Conjunctival grafts were used with a sufficient degree of success to warrant further laboratory investigation.

4. The use of a tympanomeatal flap according to the Lempert technique has given the best results, as indicated by the response to the test for fistula. A further report on this series, as well as on the use of a cartilaginous stopple, will be possible when histological preparations are finished.

A factor predisposing to success in the application of any covering graft or flap is the location of the fistula on a convex surface rather than in a localized concavity. Such a site may be obtained slightly distal to the ampulla when the posterior bony wall of the external auditory meatus and the rim of the annulus tympanicus are adequately removed.

The evidence suggests that any fistula remains open only by virtue of the union which occurs between the membranous labyrinth and the covering flap to the exclusion of the osteogenic tissue. The perilymphatic space always becomes separated from the covering flap, either by a layer of new bone or by the membranous labyrinth. Measures necessary to permit fibrous union between the membranous labyrinth and the covering flap have been shown to be:

1. Complete removal of bone fragments and endosteum from the fistula.

2. Preservation of the normal contour and position of the membranous canal, so that it makes uninterrupted contact with the covering flap.

Failure in union was commonly caused by allowing the bone fragments to slip between the bone and the endosteum or between the endosteum and the membranous canal, and by injuring or rupturing the membranous canal so that it became depressed or displaced.

JOHN F. DELPH, M.D.

Glatt, M. A.: Xanthoma or Lipoid Granuloma of the Temporal Bone (Hand-Christian-Schuller Syndrome). *Arch. Otolaryng., Chic.*, 1946, 43: 110.

A case of xanthoma or lipoid granuloma occurring in the temporal bone of a 36 year old Jewish male is reported. Symptoms of headache in the left temporal region, weakness, giddiness, and tinnitus and impaired hearing on the left side came on gradually over a 5 months' period. The patient's past history was negative except for a healed pulmonary tuberculosis occurring 9 years earlier.

Local examination disclosed redness and bulging of the superior portions of the tympanic membrane and of the anterosuperior wall of the external auditory canal. Conduction deafness of mild degree was present in the affected ear and x-rays showed an

area of destruction of the upper border of the external auditory canal and the anterior contour of the petrous bone.

At operation 3 months later a greenish-brown sequestrum was removed and with it the underlying necrotic dura. The bone surrounding the affected area was irregular and densely sclerotic. Recovery was uneventful. Healing occurred without suppuration.

Histological studies showed large endothelial cells with distinct borders, relatively small vesicular nuclei, and foamy cytoplasm with multinuclear giant cells characteristic of xanthoma or lipid granuloma.

The relation of this solitary xanthoma to the multiple lesions sometimes found in the skull, which may be associated with the Hand-Christian-Schuller syndrome, are discussed. In the presence of a solitary lesion with indefinite borders on x-ray examination, the finding of xanthoma cells in the tissues is necessary for this diagnosis. JOHN R. LINDSAY, M.D.

Jones, B. S.: Reflections on the Radical Mastoid Operation. *J. Lar. Otol., Lond., 1945, 60: 233.*

This article deals with the author's experiences in obtaining complete and permanent resolution of the discharge after a radical mastoid operation has been performed. He believes there is no reason why every patient undergoing a radical mastoid operation should not be freed from any discharge. His experiences are discussed at some length.

NOAH D. FABRICANT, M.D.

MOUTH

Desai, P.: Tumors of the Sublingual Glands (Les tumeurs de la sublinguale). *Rev. belge sc. med., 1942, 14: 278.*

Tumors of the sublingual glands are rare. The Anti-Cancer Center of the University of Liege has, since 1925, received only 1 report of such a case.

The patient was a man 46 years old. His father died of cancer, probably of the digestive tract. The patient had had pneumonia in 1920. About 5 weeks prior to the first examination, he noticed an indolent oblong swelling in the floor of the oral cavity; the swelling appeared to grow rather fast. Examination revealed an oblong tumor measuring 3 by 2 cm. on the right side in the floor of the oral cavity, extending from the lingual frenulum toward the second molar. The mucous membrane was elevated and the tumor was found to be slightly adherent to the underlying muscles. Palpation of the right submaxillary region revealed no adenopathy. Diagnosis of a probable mixed tumor of the sublingual gland was made, and excision under local anesthesia was performed and followed by radium treatment. Histologic examination revealed an epithelioma of the salivary gland of cylindromatous type. No evidence of lymph gland metastasis was found. There was no evidence of recurrence for 6 years.

The author found only 17 cases, of sublingual tumors reported in the literature, 14 of which were

classified as mixed tumors. Six of these 14 cases showed local recurrence after surgical excision, and in 2 of these pleuropulmonary metastases also developed.

It is impossible, by histological examination, to differentiate tumors with a benign clinical course from those with very malignant manifestations; therefore all tumors of the sublingual gland should be considered malignant. ARTHUR J. LIESER, M.D.

Weiss, L. R.: The Control of Bone Fragments in Maxillofacial Surgery. *J. Oral Surg., 1945, 3: 171.*

The control of bone fragments in the treatment of fractures of the facial bones is vital. The success of all fracture treatment depends greatly on stability and immobilization.

Reduction and immobilization should be attained by means of the most conservative methods possible for favorable results. There are many methods of fracture reduction and fixation, some having better results in the hands of certain men than in the hands of others. Various methods may be combined and employed together for good end results.

The head bandage has a definite place in first aid or emergency treatment. It affords stabilization to a degree, and gives the patient a sense of security and a feeling that something is being done, although it is replaced by other treatment later.

The use of wire interdentally around the necks of teeth is perhaps the oldest method for jaw fracture fixation. Many methods of wire stabilization have been offered, each with its own merits and its place. The Gilmer type is one of the oldest of present day wiring techniques. From it have been evolved most present day wire fixation methods, in which the upper jaw or the lower jaw is stabilized by its opponent. The Eby-Ivy type of fixation, the Risdon type, and the Stout continuous wire loop all employ the same principles, the purpose of which is to produce lugs or loops by which intermaxillary immobilization may be accomplished, as well as direct fragment fixation. The Stout continuous wire offers a maximum number of stabilization and traction loops and eliminates sharp projecting lugs on the buccal surfaces of the teeth.

The advantages of using interdental wire over the interdental splint are: almost immediate reduction, elimination of impression taking, time consuming laboratory procedures, and the excessive time elapsing between the time of injury and fracture stabilization; and observation of the condition of the teeth at all times, to make sure that the opposing teeth are in direct occlusion with their opponents.

The gauge of wire employed in interdental fixation should not exceed 22, and, preferably, it should be 24 or 25, since unduly heavy wire, in addition to being difficult to handle and more painful to the patient on installation, causes a definite pressure atrophy of alveolar bone, irritates the interdental papillae unnecessarily, and creates a definite gingivitis.

The arch bar attached by interdental wire loops or by tooth bands may be used for stabilization

Fig. 1. Interdental wiring with intermaxillary elastic traction; double wiring applied because of ease of installation and added loop rigidity.

Another advantage of these arch bars is that they are rigid enough to withstand considerable traction and distribute an applied force in any direction over a greater area of the dental arch than would be possible with interdental wiring, the lugs themselves offering more rigidity than the ordinary wire loop. The chief disadvantage of arch wires is that their position often produces a pressure gingivitis, since it is hard to maintain them rigidly in their original position, unless the connecting wires are placed in the beginning upon the greatest constriction of the tooth.

Rubber ligature fixation is the most universally indicated and the most adaptable type of fixation. It may be used to accomplish reduction through traction, as well as stabilization. As soon as it has accomplished reduction, its only purpose is stabilization, and it should afford just that. Many fibrous unions following rubber ligature fixation can be attributed to instability, due to the ability of the patient to counteract such traction and produce movement enough to break down the primary blood clot between these fragments. Rubber ligatures in all cases of early fracture fixation should be so strong that the patient may not counteract their traction by voluntary muscular action.

Displacement of bone fragments when the mandible or maxilla is edentulous may be reduced through alveolar wiring of the individual fragments, by the extension of wire through the alveolus of one fragment to another, and by attachment directly to adjacent stable bone, or to a bridging splint or appliance. Direct insertion of wire through the alveolar process of the maxillae to stabilize an upper denture or splint in conjunction with circumferential wiring of the mandible over a denture or splint generally produces good results in edentulous cases.

Intraosseous, intraoral, and extraoral wiring are indicated in fracture of the facial bones when it is

Fig. 2. Cast silver mandibular splint with turn buckle in lower incisor area to align fragments where there is collapse because of bone loss in symphysis area; screw extension to single left molar casting to maintain distal fragment.

impossible to maintain these fragments by other methods. This type of wiring is contraindicated in the presence of infection. It is especially applicable in fracture of the orbital ridges, mandible, ramus, and anterior end of the malar bone. Intraosseous wiring of fragments usually should be supplemented by added immobilization of some kind, whatever it may be, for alone it does not give sufficient support. These intraosseous wires may be removed or may remain permanently.

The cemented cast metal cap splint has been used extensively, especially in immobilization of complicated fractures. It is both adaptable and flexible. It may be used solely as a stabilizer, or in combination as a reducing appliance and space maintainer. Numerous connections and appliances may be incorporated in it to produce definite movement of the fragments to any extent or angle.

This type of splint lends itself to the treatment of a great many types of fractures. It may be altered by both intraoral and extraoral extensions. Extraoral extensions may be employed by attachment to

Fig. 3. Adjustable screw attachment used to control inward rotation of fragments; cast silver splint.

INTERNATIONAL ABSTRACTS OF SURGERY

this type of splint without the use of a headcap. The cast splint is indicated especially for long periods of time and in case the patient may not be under continuous supervision, or when conditions make it necessary for extensive periods of time between treatment. Good oral hygiene may be maintained with little difficulty with these appliances.

The open type of splint made of acrylic or cast metal, locking in the interproximal spaces by projections from a buccal and lingual flange and bioged in the back or in the edentulous spaces with a button attachment for closure and stabilization, is often indicated when all or some of the teeth are affected because of trauma, decay, or periodontoclasia, and as a result are loose and of questionable stability.

The use of external pin fixation has been very much talked about, especially in recent years. External pin fixation has a definite place in fracture reduction and in fixation of the mandible, but it should be used only when there is no other method of obtaining satisfactory reduction and stabilization. It is indicated in cases of extreme loss of osseous tissue in the angle, in the body and angle, in the edentulous jaw, or in the bilateral condyle fracture when the mandible is edentulous.

Intraoral pin fixation has little if any value in reduction and stabilization of any type of fracture with the exception, possibly, of fracture of the angle or of the ramus of the mandible. Its great hazard is the possibility of infection and ensuing loosening of the pins.

Headcap traction as a method of producing stabilization is often indicated, and sometimes offers the only method for stabilization of the part. Attachments, extensions, and fittings of various types may be employed, the resulting traction assuring stabilization or extension in almost any direction or angle. Its stability depends on its covering the external

occipital protuberance and its enveloping the traid process. The plaster headcap, which has stood the test of time, is very adaptable to any desired appliance, but, unfortunately, it is uncomfortable to many patients.

The greater number of fractures coming under the maxillofacial surgery department, being the result of gunshot wounds, show such loss of bone that bridging or approximation cannot be accomplished without loss of function and facial distortion. Statistics from World War I indicate that about 11 per cent of gunshot fractures result in nonunion and require bone grafting. Since, in nearly all of the author's cases, the bone was comminuted and shattered, and often became infected, some necrosis and sequestration resulted. Sequestration can be held to a minimum by early stabilization of the fragments. Immobilization should be secured by splints or appliances stable and rigid enough to withstand all muscle pull and action, as bone grafting requires absolute stability and over a long enough time for the graft to 'take' without disturbance of its position, which must be held by a rigid trouble-free appliance.

No one type of splinting for fragment stabilization in bone graft preparation can be advocated. When teeth are present, the closed cap cast interlocking pin and flange splint furnishes the desired stabilization, being attached by cement to the teeth and otherwise by interdental wires. Bone graft stabilization in the edentulous mandible is a problem that must be met entirely by the ingenuity of the surgeon. It must be accomplished entirely by extraoral fixation either from a headcap, by means of a bar, pin, or wire extensions, or by direct bar or pin fixation, the pins or bar lying far enough from the site of the graft itself not to endanger it from infection, which often results through the communication of bone with the surface of the skin by means of the pin itself.

FREDERICK W. MERRIFIELD, M.D.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

De Girardier, J.: Late Reactions following Nerve Suture with Integral Physiologic Restoration of the Nerve (*Durée réflexogène tardif d'une cicatrice de suture nerveuse réussie avec restauration physiologique intégrale du nerf*). *Lyon chir.*, 1945, 40: 33.

A 10 year old girl suffered a deep laceration just above the right elbow which severed the radial nerve and caused typical radial paralysis. The wound was treated 4 hours after its occurrence by careful cleansing and débridement, suture of the nerve ends, and primary closure. The arm was immobilized in a neutral position for 3 weeks, and after 4½ months was functionally as good as the left.

Four years later, however, symptoms suddenly appeared in the right forearm, at first intermittent, but later constant. These consisted of paralysis, paresthesias of the fingers and hand, vasomotor reaction of the skin of the hand and fingers, and a tenderness of that part of the scar directly over the nerve course. Movements of the right hand were decreased, especially wrist extension and finger flexion, and forceful movements were impossible. Finger edema was noted. Examination of the scar showed a slight swelling directly over the nerve trunk, and pressure at this point caused pain which radiated along the posterolateral part of the forearm.

Five months after these symptoms had begun a right stellate injection was performed with immediate relief of all symptoms. An acetylcholine-papaverine mixture was prescribed. Several months later, however, the neuroma again became painful and vasomotor phenomena reappeared. Soon the symptoms became as intense as during the first occurrence. An injection of procaine was made at the neuroma site. This resulted in cessation of the symptoms but the relief was of short duration. It was necessary to give a stellate ganglion injection two more times, but at the time of this report, no symptoms had recurred for more than a year. When and if they reappear, a perihumeral sympathectomy is planned.

A possible relation of the reflex vasomotor reactions and other symptoms to menstruation, since the exacerbation of the symptoms began with the onset of puberty, is suggested.

C. FREDERICK KITTLE, M.D.

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Munslow, R. A.: Penetrating Head Wounds. *Ann. Surg.*, 1946, 123: 180.

The author reports his experiences with 140 cases of penetrating wounds of the brain divided into 3 groups on the basis of the tactical situation under

which they were treated. The material resulted from the Italian campaign and is presented in a statistical manner.

Ninety per cent of the wounds were caused by shell or mortar fragments and only 5 per cent by small arms fire. Twelve per cent of the patients were admitted in a state of clinical shock, and in 9 of these patients the shock was attributed to the head wound, and in 3, to other associated wounds. Thirty-six per cent of all the patients had also other wounds of the body. Consciousness was preserved in 78 per cent of the patients, although the criteria for consciousness is not defined. Approximately half of the patients had a missile within their craniums upon roentgen examination, the other half had only indriven bone fragments. In 10 per cent of the patients, the paranasal sinuses were injured.

Local procaine infiltration alone of the scalp was used for débridement and repair in 64 per cent of the patients, while intravenous sodium pentothal was used as a supplementary agent in 26 per cent. The average operating time was 1 hour and 40 minutes.

The surgical treatment consisted of débridement and excision of the scalp wounds, the making of a craniectomy for exposure and débridement of the missile tract of all bone fragments, necrotic brain substance, and extraneous material. This was accomplished by use of the suction apparatus under direct vision. The author has not hesitated to use an exploring finger in the brain to search for deeply indriven bone splinters, a procedure which is indispensable if all bone chips are to be found. The author points out that very small metallic missiles within the brain do not present enough hazard of infection to warrant the destruction of brain tissue involved in their extraction.

The missile tracts involved one hemisphere in 70 per cent of the cases and both hemispheres in 21 per cent. Tracts crossing the midline resulted in fatality twice as often as those confined to one hemisphere.

Early in the campaign sulfanilamide was dusted into the débrided cerebral wounds but this was discontinued later. In the last half of the series, 10,000 units of penicillin were instilled into the clean cerebral cavity before closure of the wound. Tight closure of the dura was accomplished in half of the cases and fascia lata grafts were employed when the ventricles had been penetrated.

The sulfonamides were employed in the post-operative management for prophylaxis against invasive infection until penicillin became freely available. Then, 25,000 units were given intramuscularly every 3 hours for 5 days.

There was an operative mortality of 17 per cent. Of 109 soldiers who survived, 103 were observed in follow-up examinations, an unusually good record. Full neurological recovery had been made by most of the patients and 16 per cent had been returned to

duty status. Eighteen patients required secondary craniectomy at the Base Hospitals for various causes, 8 for late abscess.

The author's experiences and conclusions for the most part parallel those of other surgeons who have treated cranial wounds in the combat zones during the war.

LAURENCE M. WEINBERGER, M. D.

Rand, C. W., and Courville, C. B.: Histological Changes in the Brain in Cases of Fatal Injury to the Head. Alterations in the Nerve Cells. *Arch. neur. psychiat.*, 1946, 55: 79.

This article is one of a series dealing with the various cytological changes in the brain following injury to the head. In the total investigation, the authors have been concerned with an explanation, if possible, of the residual symptoms which often persist after head injuries, and with a study of the detailed changes in the various parts of the brain. They found that a generalized chromatolysis of the cortical ganglion cells is the usual response of the brain to severe injury. They assume this to be the histological side of the picture of "commotio cerebri," or concussion, but they do not insist that such changes are necessarily the cause of the change in the psychic realm so often seen in such injured persons. They point out also that "one should not attempt to account for temporary loss of consciousness, with restoration to the normal state in that respect within a few hours, on the basis of alterations in the nerve cells which persist for at least a month, or over."

Following acute trauma, there is a disturbance in the fluid balance of the cerebral tissues, with anatomical alterations within the cells on that basis alone, and it is the combination of the effect of the shock and edema that produce the cellular alterations so consistently seen in the cerebral and cerebellar cortex after acute injury. Local, prolonged pressure upon the cortex, as in a depressed fracture, may produce reversible changes if the pressure is of a moderate degree, and consists of a loss of the tigroid substance and eccentrication of the nucleus. The more severe and prolonged pressure results in local degeneration, due, most likely, to regional anemia rather than to any mechanical effect. Not unless the cortex is actually bruised at the time of depression is such an injury accompanied by any marked degree of change in the cortical cells.

A review is made of the important contributions to the neuronal changes incident to severe destructive lesions of the cortex. These changes are dependent not only upon the original shock, but also upon circulatory deficiency, such as hemorrhage, edema, ischemia, and possibly some local anoxemia. Many of these same conditions exist in other pathological conditions of the brain, but in the instance of traumatic lesions multiple types of change may be found within a single cell.

The authors have evidence to support several conclusions. Cells at the site of trauma may be killed immediately or may die after a variable delay,

according to their degree of direct injury and proximity to the point of greatest force. Cells outside the site of primary injury may survive, or they may, after a period of days, gradually die and fade out. They may show, therefore, either local or general effects of injury. They may live to recover from such changes as loss of tigroid substance or infiltration of hematogenous pigment. Too, some cells may survive but remain worthless to the organism's economy thereafter. Dead and "crippled" cells may become encrusted with iron (ferrugination, "calcification"), and are actually mummy cells in such a state. It is characteristic of the alterations in cells injured by acute trauma that such changes are multiple within each cell. There may be, in the same cell, the so-called "preservation necrosis of Cajal," alterations in the Golgi apparatus, infiltration of pigment, pyknosis, edema and vacuolization, ischemic changes, lipoidal degenerative changes, segmentation of the cell and its membrane, and physicochemical alterations in the cytoplasm. The tigroid substance may undergo profound loss, the neurofibrillae may show marked disintegration, and the cells may become multinucleated. There is one colored plate with the text which beautifully illustrates these various possibilities of cellular alteration.

JOHN MARSH, M. D.

Echternacht, A. P., and Campbell, J. A.: Midline Anomalies of the Brain; Their Diagnosis by Pneumoencephalography. *Radiology*, 1944, 4: 119.

Congenital cysts of the septum pellucidum and of the associated structure, the cavum vergae, are not of frequent occurrence and are always diagnosed either by pneumoencephalography or by incidental finding in the autopsy specimen. The previous literature contains 15 reported cases of congenital cysts of the septum pellucidum, and the 5 cases of the authors bring the total to 21. These 5 cases were found in a total of 96 pneumoencephalograms, rather a high percentage, which suggested that such developmental anomalies are frequently overlooked in the reading of such roentgenograms.

The cysts which communicate with the true ventricular system (this communication may actually be artifactual) will show with characteristic shadows in the roentgenograms, but those of the noncommunicating type will show only through their "negative" shadow and by the distortion they produce on the surrounding portion of the brain and on the ventricular shadows.

The authors report 2 cases of agenesis of the corpus callosum, a developmental phenomenon sometimes associated with changes in the septum pellucidum. This makes a total of 20 such cases reported to date in the literature.

The midline developmental defects may be associated with mental abnormality, epilepsy of undetermined origin, and other obscure neurological conditions. There is no evidence in any of the reported cases that sex is a determining factor, and the

age of the patients has varied from the time of birth to 73 years.

JOHN MARTIN, M. D.

Mathewson, W. R.: Meningioma of the Tuberculum Sellae with Bitemporal Hemianopia. *Brit. J. Ophth.*, 1946, 30: 92.

The author presents a case report of a prechiasmal meningioma with typical early signs and symptoms and progression to partial optic atrophy in both eyes before surgical intervention. Associated bitemporal hemianopic field changes were found in both eyes, being more marked in the right eye in which central vision also was impaired to 6-60.

The field changes in the preoperative phase progressed typically in the temporal halves superiorly, and in the reverse order postoperatively. A method for facilitating the field examination when one eye has lost fixation is described, wherein complementarily colored and green glasses on opposite eyes, a correspondingly colored test object, and a white fixation light are used.

HUNTER H. ROMAINE, M.D.

List, C. F., and Holt, J. F., and Everett, M.: Lipoma of the Corpus Callosum; A Clinicopathological Study. *Am. J. Roentg.*, 1946, 55: 125.

The corpus callosum appears to be one of the favorite sites of cerebral lipoma. The world's literature contains 30 cases involving the corpus callosum among a total of approximately 100 known examples of lipoma of the brain.

The authors report a case with a complete history, neurological examination, electrocephalograph, and roentgenograms. This case was operated upon and they give the sequence of events following the operation. A second case is also described and the autopsy findings recorded.

Even though the clinical symptomatology is not pathognomonic, the diagnosis of lipoma of the corpus callosum can occasionally be made during life by roentgenographic means. The roentgenographic signs consist of increased radiolucency of the tumor, calcification, demonstration of an expanding mass in the anterior part of the corpus callosum, and agenesis of the posterior portion of this structure.

Surgical treatment of lipoma of the corpus callosum is contraindicated.

PAUL MERRELL, M. D.

SPINAL CORD AND ITS COVERINGS

O'Connell, J. E. A.: The Diagnosis of Lumbar Intervertebral Disc Protrusions. *Brit. M. J.*, 1946, 1: 122.

Posterior crural, or sciatic, and anterior crural pain are familiar symptoms. In the past the commonly accepted view has been that such pain results from an interstitial neuritis of the sciatic or anterior crural nerves, or that it is referred from lesions of the muscles, ligaments, and joints of the lower back. While the patients with milder cases recover with a variety of treatments based on these etiological hypotheses, the results of such therapy have been

disappointing in the more severely affected patients. During the last 10 years much light has been shed on the etiology of these crural pains by neurosurgeons, led by Mixter (Mixter and Barr in 1934, and Mixter and Ayer in 1935).

Evidence has gradually accumulated to suggest that, at least when the symptoms are severe, their far most common cause is a lumbar intervertebral disc protrusion. The presence of anterior crural or sciatic pain should therefore immediately suggest the possibility that a protrusion of a lumbar intervertebral disc has occurred. This possibility becomes a probability if the leg pain is associated with a characteristic series of physical signs in the lumbar spine and affected lower limb.

A variety of different lesions may occasionally give rise to the syndrome under discussion. The author points out that a tumor within the spinal canal, inflammatory or malignant disease of the spinal column, and spondylolisthesis most commonly cause the described pain. He discusses the importance of a very complete neurological examination and believes that in the majority of cases the extent of a lumbar intervertebral disc protrusion can be discovered by clinical examination alone. Roentgenography usually is the only accessory method of examination that need be routine. The presence of an intervertebral disc protrusion may be revealed by narrowing of the intervertebral interval and perhaps some localized osteoarthritic change. He discusses the use of lumbar puncture with manometry and examination of the cerebrospinal fluid as an aid in differentiating between neoplasms and protrusion of an intervertebral disc.

The author then considers the indications for operation and attempts to give the essential differential points between those lesions which may cause pain. He gives the indications for operation, three aspects being considered: the severity and duration of the symptoms, the severity of the neurological signs, and the severity of the tension signs. He discusses the examination to bring out these features. He stresses that during the neurological examination it is well to remember the anatomy and distribution of the nerves so that one is able to localize the intervertebral disc protrusion and operate at the proper level.

The author states that he bases his observations upon the clinical and operative findings in a personal series of more than 220 proved cases of lumbar intervertebral disc protrusion.

PAUL MERRELL, M. D.

White, J. C., and Peterson, T. H.: Lumbar Herniations of the Intervertebral Discs; the Value of Surgical Removal for Naval Personnel. *Occup. M.*, 1946, 1: 145.

Although excision of protruding intervertebral discs should give relief to patients presenting low backache and sciatica, and no additional weakness of the lumbosacral region, such is not always the result. A review of the literature covering 957 cases reveals that the results were classed as from excellent

to good in 67.58 per cent, as improved in 17.08 per cent, and as unsatisfactory in 15.33 per cent. This discrepancy is attributed to changes in the spinal ligaments, articular facets, and laminae which are overlooked even in a careful survey during operation. Relatively few articles concerned with the surgical result of this condition among military personnel have been published. The authors present 39 naval patients operated on with the removal of a definitely herniated disc. Only those who failed to respond to conservative orthopedic management after a month were submitted to surgery. Besides the neurological signs of root compression, a definite filling defect in the pantopaque spinogram was found in all but 2 of the patients. One hundred and one patients with a clinical suggestion of prolapsed intervertebral disc were examined by this method and 56 were returned for nonoperative treatment in the absence of any projection or root sheath filling defect. Two patients were operated upon after normal spinograms were observed because of their definite symptoms, elevated spinal protein, signs of root compression, and failure to respond to conservative orthopedic management. A disc herniation was present in both.

The surgical technique was constant for all operations. Subarachnoid block was the type of anesthesia used. After removal of the muscle from three spinous processes, little or no bone was removed from the contiguous laminae, but extradural removal of the herniated fibrocartilage mass was done. The interspace was then curetted to collect fragments which might subsequently become loose. In each case the adjacent vertebrae were tested for mobility, and the exposed ligaments and articulations were examined for evidence of trauma or malformation, but only one primary spinal fusion was necessitated because of such findings. Postoperative convalescence permitted these men to void while standing on the evening after operation and they were encouraged to sit and move about the next day. Generally in less than 2 weeks, with daily sitting up exercises, these patients were ambulatory. Between 1 and 4 months postoperatively they were discharged to limited or full duty. The ages of the patients varied from 20 to 54 years. Two instances of postoperative sepsis were present but they were not of major import. Some of the patients required catheterization for brief periods. One patient with an unusually large disc had preoperative bladder paralysis, but recovered normal function in 9 days after the operation.

When these patients were admitted to the neurosurgical division it was evident that unless their pain could be alleviated they would require discharge. After operation only 1 has been discharged for medical reasons although the retention in service of 7 others is uncertain. As civilians all of them should be able to do light work and not require total disability pensions. Of 24 patients whose followup extended from 5 to 30 months, 54.2 per cent (13) were classed as having excellent results, 20.8 per cent (5) as having good results, and 20.8 per cent (5) as having uncertain results; and in 4.2 per cent (1) the result

was considered a failure. Therefore, 75 per cent had results both useful to the service and satisfactory to the patients. The remaining 25 per cent is composed of 2 patients who have difficulty in a limited service status, 3 who are hospitalized for further treatment, and 1 patient who is discharged from service but does light civilian work. Of the remaining 15 on whom statistics were available only up to the time of their hospital discharge, 3 were sent directly to duty, and 10 to limited duty or to a naval convalescent unit with a good prognosis. Two had uncertain results. Many men have written subsequently, enthusiastic over their sound physical condition.

Four of the 39 patients had multiple disc herniations. Most of these occurred without a history of additional trauma. There were 3 instances of recurrent pain due to further rupture of the annulus fibrosus and compression of the nerve roots at other sites, and 4 other patients suffered disability after initial successful results. Of these 7 cases, 3 were due to further disc ruptures at other sites, 3 were due to further spinal trauma, and 1 was due to failure to fuse an obviously unstable lumbosacral spine.

During the period when these 39 cases were treated there were 7 other exploratory operations made in which this diagnosis was not substantiated. Hypertrophy of the ligamentum flavum, traumatic swelling of the posterior root ganglion, and neurofibroma of the cauda equina were lesions which had caused filling defects on the spinogram and presented a clinical history suggesting ruptured intervertebral disc.

The authors believed that primary spinal fusion was indicated only when structural defects in the vertebrae are obvious. All ligaments, laminae, and articular facets exposed should be critically examined during the operation with this orthopedic aspect in mind. Indications for fusion are those suggested by Ghormley, Love, and Young: spondylolisthesis, spondylolysis, extensive lumbosacral arthritis or bursitis, spondylitis, congenital anomalies such as abnormal sacralization of the lowest lumbar vertebrae, and abnormalities of the neural arch or of the vertebral body, with apparent instability of the vertebra at the time of operation. The history is significant in that only those patients who are relieved by rest and have pain on activity are suitable candidates for fusion. In this series 1 primary fusion and 2 secondary fusions, for later herniations, were done.

The relatively high rate of good results is attributed to the care with which the operative patients were selected. Only those with filling defects and failure to respond to orthopedic care were submitted to operation.

C. FREDERICK KITTLE, M.D.

SYMPATHETIC NERVES

Tyson, M. D., and Gaynor, J. S.: Interruption of the Sympathetic Nervous System in Relation to Trauma. *Surgery*, 1916, 19: 167.

Interruption of the sympathetic nervous system applies chiefly in 3 general categories, in all of which it

is used to improve the circulation at the site of the trauma. These groups are as follows:

(r) Post-traumatic painful and vasospastic states, with or without Sudeck's osteoporosis. This group includes those cases in which reconstructive surgery is contemplated in the face of a dangerously reduced circulation.

(2) Injury of the main arterial supply of an extremity.

(3) Acute trauma, particularly fractures and crushing injuries to the hands and feet.

Cases demonstrating all of these groups are discussed.

The authors conclude that cases of these types should first have a novocain block to see whether any improvement results. If there is marked improvement which disappears after the effects of the novocain wears off, and the condition is sufficiently serious, permanent interruption of the sympathectomy fibers is indicated. It is believed that this may result in marked reduction of the disability, pain, and period of hospitalization. JOHN W. EPPON, M.D.

Peet, M. M., and Isberg, E. M.: Surgery for Hypertension. *J. Am. M. Ass.*, 1946, 130: 467.

Between the dates of November, 1933, and September, 1945, more than 1,500 patients received surgical treatment for hypertension at the University Hospital at Ann Arbor, Michigan. The operations consisted of bilateral supradiaphragmatic splanchnicectomy and lower dorsal sympathetic ganglionectomy. Of these patients, 437 with essential hypertension were followed up for from 5 to 12 years after surgery, and 57.5 per cent are living from 5 to 11 years after surgery. Eighty-two per cent of the patients had serious organic disease prior to the operation, but 95 per cent of the hypertensive patients who showed no signs of cardiac, cerebral, or renal involvement before the operation are living from 5 to 11 years after surgery. A third of all patients who manifested preoperative disease of the heart, brain, or kidneys did not survive the 5 to 11 year period.

It is pointed out that a complete clinical profile of the patient must be obtained before surgery is undertaken, since it is never an easy task to determine just what patient will benefit by surgery or survive long enough to make the procedure worth while. This profile consisted of studies for renal function and cardiac efficiency, fundoscopic examination, frequent blood pressure recordings, and detailed physical examinations and careful history taking. Favorable changes in the drop in blood pressure with resultant improvement in the subjective complaints of the patients, significant improvement in kidney function, and protection against repeated cerebral vascular accidents in those patients who had had such complications, have been found to be the result of surgery in a gratifying number of patients. For these reasons the authors believe that the life span of the hypertensive patient may be significantly lengthened by surgical treat-

ment, although it is admitted that the "hypertensive predisposition" always persists following surgical treatment, regardless of the fall of the blood pressure to normal levels, and that no claim should be made that essential hypertension is cured by splanchnicectomy.

JOHN MARTIN, M. D.

MISCELLANEOUS

Houston, H. E.: The Neurosurgical Service in an Evacuation Hospital. *Bull. U.S. Army Med. Dept.*, 1946, 5: 328.

This is a report on the neurosurgical cases seen in an Army evacuation hospital. Of 1,393 cases cared for on the neurosurgical service, 406 were considered closed head injuries. Approximately 80 per cent were the result of blast and in the remainder the head of the patient had struck or had been struck by some object. No differentiation was made in the two types of injury as it was believed that the less severe blast cases behaved much like concussions from direct force. The more severe ones resembled basilar skull fractures. The chief difference seemed to be the associated ear and lung damage in the blast variety. There were 14 deaths in this group. All of the patients had been admitted while profoundly unconscious, with no localizing signs. No therapy seemed of value in these serious cases and they deteriorated. Autopsy in 2 cases revealed multiple petechial hemorrhages in one and ventricular hemorrhage in the other. Two patients were explored for suspected subdural hematoma with negative results.

Scalp lacerations were treated by conservative débridement and closure of the galea and skin layers with interrupted silk.

Simple fractures were treated as the closed head injuries, but the compound fractures were debrided and closed. Penicillin and sulfadiazine were administered for 4 days or longer. With compound depressed fractures, the depressed area was approached through a burr hole in the normal skull, the entire involved area excised, and the dura closed with silk if opened.

Of 271 patients with penetrating brain injuries, 69 died without surgery. The treatment of shock was given priority over operative care in this group. Less than 50 per cent required shock treatment of some sort and only 10 per cent required intensive shock treatment. Barbiturates and morphine were used to control restlessness and no untoward effects were noted from the use of morphine. The optimum time for surgery appeared to be between 18 and 24 hours following the injury. The single exception to such delay in surgery was in the case of ventricular wounds; these cases deteriorated rapidly if not subjected to surgery. Penicillin and sulfadiazine were employed, and preoperative medication consisted of 3 gr. of sodium amytal, $\frac{1}{4}$ gr. of morphine, and 1/150 gr. of atropine. The anesthetic agents included pentothal sodium, intratracheal gas-oxygen-ether, and novocain. In at least 85 per cent of the cases pentothal sodium was used. The primary wound was de-

bridged and extended in a linear manner, and the bone around the wound removed to secure a normal dural margin of $\frac{1}{4}$ inch. Necrotic brain and hematomas were removed with suction. Bone fragments and foreign bodies were removed under direct vision when practicable. Finger exploration was carried out if space permitted, and, finally, the tract was irrigated, a catheter being used if the ventricles were involved. If possible the dura was closed with interrupted silk; if not, the defect was closed with a detached pericranial or galeal graft. The galea and skin were closed with interrupted silk sutures, penicillin and sulfanilamide powder being placed in all of the wounds. If the scalp defect could not be closed, a flap extending down to the periosteum was mobilized and advanced to close the bone defect completely. Wounds involving the paranasal sinuses were treated similarly, except that exenteration of the sinuses was carried out. Dural closure or graft and skin closure seemed particularly important in this group. The head dressing of choice was an unpadded plaster cast.

The prognosis in the cases with ventricular damage was very poor; 12 of the 18 deaths among 201 cases operated on were in this group. The postoperative care consisted of the continuation of penicillin, sulfonamides, and crystalloids, and plasma and blood as indicated. Diet and activity were allowed as

tolerated. Patients were evacuated as soon as they were oriented, taking food well, and relatively afebrile. The average postoperative stay was from 4 to 6 days.

Of 85 patients admitted with injuries of the spinal cord or cauda equina, 37 were admitted with associated wounds of the chest or abdomen. The latter injuries were given priority in the treatment. Nine laminectomies were done because of nontransportability to a neurosurgical center. Twelve cases presented complete transection of the cord above the level of the third dorsal segment. Immediately on admission, these patients were given indwelling catheters, x-rayed, and transferred to a well padded litter. If evacuable, they were given highest priority to a neurosurgical center. The prone position was favored in lower lumbar and dorsal injuries, and the recumbent position in upper dorsal and cervical injuries. Casts were employed only for those with an unstable vertebral column. Patients having laminectomies were premedicated with sodium amytal, morphine, and atropine. The operation was as limited as possible. The metallic and bony fragments were removed, the dura closed with silk or with a fascial graft. Complete closure of the soft tissues was carried out. Evacuation was carried out in from 4 to 6 days.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Campbell, O. J.: The Bleeding Nipple. *Surgery*, 1946, 19: 40.

The significance of a discharge from the nipple, particularly a bloody discharge, has been variously interpreted. Some workers have found about the same proportion of benign and malignant lesions responsible for this symptom.

Undoubtedly the difficulty in distinguishing between actively proliferating adenocystic disease and cancer has complicated the problem of determining the true incidence of malignancy in patients with a bloody discharge. Sanguineous discharge from the nipple is not a common symptom.

It has been shown that duct papilloma, carcinoma, and cystic disease are responsible for most of the cases of bloody discharge from the nipple. Other etiological factors, however, are inflammatory lesions, traumatic lesions, hormonal dysfunction, sarcoma, and Paget's disease.

The character of the discharge is merely suggestive, but all types of discharge (with the exception of galactorrhea) need investigation.

Diagnosis is essentially a problem for the pathologist. Frozen sections are not to be relied upon. Because cancers associated with bleeding from the nipple are usually of low malignancy and also because the differentiation between cancer and adenocystic disease may be difficult, the surgeon should permit the pathologist time to prepare and study permanent slides.

In the absence of palpable tumor there are three diagnostic aids for the localization of the source of bleeding: (1) transillumination, (2) mammography, and (3) pressure tests.

Suggested treatment procedures consider the following:

A. Discharge and palpable tumor. The presence of the tumor alone is sufficient justification for its removal. Local excision may suffice for solitary intraductal papillomas and well localized adenocystic disease, but because the sources of bleeding may be multiple it is better practice to excise the entire duct and tributary glands. Only when the pathologist has satisfied himself that the lesion is malignant is radical amputation justified.

B. Discharge and diffuse nodularity. A segmental resection of the duct containing the bloody discharge and its tributary system is done. If cancer is not found and the source of bleeding is eliminated the attitude toward the remaining breast will depend upon the surgeon's attitude toward cystic disease as a potentially precancerous lesion.

C. Discharge and no palpable tumor or demonstrable breast change. Whenever the source of bleeding can be located the offending duct and tributary glands are excised. When the discharge

is intermittent or scanty it may be difficult to locate the segment of breast or the duct from which the discharge is coming. Under these circumstances it seems entirely reasonable to keep the patient under observation. Repeated examinations will usually permit localization. The justification for this policy is based upon the extreme rarity of sanguineous discharge from the nipple caused by cancer and without palpable tumor.

D. Bloody discharge from multiple sources. A waiting policy is here indicated unless palpation reveals changes in breast consistency which then justify biopsy of the most suspicious area. Bleeding of such nature may subside spontaneously.

E. Pseudosanguineous discharge. A dark green, sometimes grumose discharge from the nipple may easily be mistaken for bloody discharge. When a single duct is the source, excision is warranted for the patient's peace of mind. The excised duct will show ectasis only. There will be little or no sign of epithelial activity. The dilatation may involve even the smaller tributary ducts in the periphery of the breast. When multiple ducts are involved and no masses except the ducts themselves are palpable, the condition need not be disturbed since sacrifice of the whole breast is unnecessary.

F. Persistent or nonlocalized bleeding. Persistent bleeding from multiple sources or bleeding which cannot be localized may warrant simple amputation. Especially is this true in older women in whom the loss of the breast is not a tragedy, or when the patient herself may elect to end her state of uncertainty or apprehension. STEPHEN A. ZIEMAN, M.D.

Costello, C. J.: Breast Cancer and "Paget's Disease of the Breast." *Arch. Surg.*, 1945, 51: 262.

This study, which has been prompted by the evidence of confusion and the divergence of opinion among clinicians and pathologists alike as to the nature of so-called Paget's disease of the breast, embraces a thorough review of 29 cases as well as a review of the studies and observations by other investigators of this malady. The origin of the dissection emanates from confusion in regard to the cause and significance of, and consequently the therapy indicated for, Paget's disease.

What has been called "Paget's disease of the breast" begins as an intractable eczema of the nipple or areola. The patient's first recollection of the onset is as often recurring pruritis of the skin in this region. Again, the first symptom may be a simple crust associated with weeping or even bleeding of a minor character when it is removed. In some instances the first bleeding is noted to come from the summit of the nipple, although this may not correspond with the center of the cutaneous lesion.

Certain resemblances exist between Bowen's and Paget's diseases. Generally, Bowen's disease is con-

sidered to be a primary epithelial malignant growth of low grade and slow progression. The chief distinguishing feature is that in Paget's disease there is actual dissociation of the abnormal cell, whereas in Bowen's disease the cell continuity with the adjacent epidermal cells is retained and the intercellular bridges in the rete malpighii are preserved.

Paget cells appear to be metastatic cancer cells. The origin of Paget cells may be from breast carcinoma, epithelioma, rectal adenocarcinoma, apocrine sweat gland carcinoma, or other tumors.

In order to insure earlier recognition, refractory eczematoid lesions of the breast should be subjected to biopsy. The mode of extension may be by direct extension, retrograde lymphatic continuity, or ductal spread.

In order to reduce confusion among pathologists and clinicians and in order to facilitate earlier and more rational therapy, the eponymic nomenclature, "Paget's disease of the breast" and "extramammary Paget's disease," should be abandoned; "secondary epidermal carcinoma" is suggested as preferable.

Treatment of secondary epidermal carcinoma must proceed along the lines of rational elimination of the primary carcinoma as well as of the cutaneous lesion. In order to insure a higher curability rate, treatment for secondary epidermal carcinoma of the breast must include radical mastectomy, whether the primary site can be detected by palpation or not.

JOHN E. KIRKPATRICK, M.D.

Oberhelman, H. A.: Diagnosis and Treatment of Carcinoma of the Female Breast. *Surg., Clin. N. America*, 1946, 26: 116

Pain is not a diagnostic sign of carcinoma of the breast. In one series of 1,040 cases, only 1.6 per cent of the patients came to their doctor because of pain. In only 3 per cent of 500 cases of carcinoma of the breast were there more than one nodule. The author believes that so called horderline or precancerous lesions, which occur almost exclusively in the proliferative and hyperplastic form of fibrocystic disease, call for radical surgery. It should be remembered that carcinoma can develop in accessory breasts; 2 per cent of all mammary carcinomas develop in women under 30 years of age.

The author follows the operative technique of Adair, by which the pectoralis fascia is removed but the pectoral muscles are preserved. Postoperative radiation therapy is used. Local recurrence is treated by local excision of the tumor mass followed by vigorous irradiation. Sometimes in these cases irradiation alone is used.

EARL O. LATIMER, M.D.

White, W. C.: The Problem of Local Recurrence after Radical Mastectomy for Carcinoma. *Surgery*, 1946, 19: 149.

The author reports 22.6 per cent of local recurrences among 238 cases of carcinoma of the breast. The patients were observed for a minimum of 5 years. This rate of recurrence compares favorably with statistics from other clinics.

The percentage of local recurrence in cases with axillary involvement was tripled over that in cases with cancer limited to the breast.

The rate of local recurrence was essentially the same if a wide excision of the skin was done and the defect covered with a skin graft, or if a plastic closure was done by removing a circular diameter of about 5 inches of skin (Handley technique) and effecting a plastic closure of the defect by means of dissection of the subcutaneous tissue of the remaining skin.

In the author's experience postoperative irradiation did not reduce the incidence of local recurrence

EARL O. LATIMER, M.D.

TRACHEA, LUNGS, AND PLEURA

Johnson, J.: Battle Wounds of the Thoracic Cavity. *Ann. Surg.*, 1946, 123: 321.

This article presents the experiences encountered in North Burma from December, 1943 to March, 1945. Three hundred and eight patients were treated in the General Hospital for wounds of the thoracic cavity; of these, 6 were due to bayoneting, 153 to bullets, and 149 to fragmentation missiles. The patients were predominantly Chinese. At least 60 per cent of them were received within 36 hours after wounding, although some were received after 3 or more weeks.

The initial treatment was carried out in portable surgical hospitals under primitive circumstances. The management was conservative in the main, essentially débridement and closure of the chest wall with only an occasional intrapleural procedure. The work of the forward units was highly commended. Evacuation was largely by air.

The patients requiring emergency treatment on arrival at the base were those with (1) blood loss and shock, (2) disturbance of the mechanism of respiration, or (3) combinations of these.

There were 140 hemothoraces or hemopneumothoraces; 103 were treated by thoracenteses. The small number left untreated required a long hospital stay or developed thoracic disability. If infection occurred in these cases, the empyema was larger than if aspiration had been done. Air replacement is condemned. Recurrence of the pulmonary bleeding did not occur as a result of thoracentesis. Fever was frequently present, but persisted only in the infected cases. Infection in the underlying lung may account for this phenomenon. Clotting, or the loculation of pleural fluid from other cause, occurred in 8 per cent (11 patients). Eight of these 11 patients were infected. Only 1 patient was subjected to decortication, and from experiences gained earlier in the campaign, this is the recommended treatment.

Tension pneumothorax was treated by repeated thoracenteses or catheter decompression if the rapidity of the reaccumulation of air justified this. After 4 or 5 days, negative pressure may be added to the water-seal to promote pulmonary expansion. There were 50 patients who had sufficient shift of the

Fig. 1. Method of applying suction to an open thoracostomy. A. The fingers but not the thumb are cut from a rubber glove. The tip of the thumb is cut away. The glove is then cut along the ulnar aspect. This will then open to form a sheet of rubber tissue with the thumb in the center. B. A large rubber tube is then put through the thumb and glued to it. The tube is connected with an ordinary three bottle Wangenstein suction apparatus. C. The skin around the empyema opening is painted with the glue used with the Padgett dermatome for removing skin grafts. A little gauze packing is placed around the tube to absorb any ex-

cessive fluid until the rubber tissue is stuck. The rubber tissue is then held moderately taut and placed down smoothly on the skin surface. The tube must already be connected to the suction apparatus so that suction can be applied immediately. This will pull the rubber tissue tightly against the skin surface so that it may become effectively glued. The edges of the rubber tissue are covered with adhesive. When carefully applied this air tight seal is effective for from 10 to 14 days. With the Wangenstein suction apparatus a negative pressure of up to 150 cm. of water can be attained. (Courtesy of J. B. Lippincott Co.)

mediastinal structures to be diagnosed upon clinical examination.

Subcutaneous emphysema was seen in 29 patients. In only 2 was it massive. Relief of a tension pneumothorax corrected this in 1 patient. The other, having a wound of the trachea, low in the neck, required tracheotomy to prevent expulsion of air into the tissues on coughing. This management for certain types of tracheal wounds is discussed and recommended.

Lung wounds were treated conservatively. In only 2 instances did lung abscess develop and both of the patients died as a result of multiple abscesses. Rather rapid clearing of the lung hematoma was a common experience.

The fundamental objective in the treatment of empyema is to obtain adequate drainage and achieve re-expansion of the lung as rapidly as possible. Earlier in the campaign, aspiration over a period of time sufficient to allow for fixation of the lung to the chest wall was undertaken to prevent a total pneumothorax when rib resection drainage was done. This, however, as well as intercostal drainage, was

interfered with by difficulty in accommodating the heavy exudate to the lumina provided. Later, therefore, drainage was undertaken much earlier when, under intratracheal anesthesia, a large sized opening was made in the chest by removing the segments of two ribs and intervening muscle. All the exudate was then removed and closed drainage with suction to 150 cm. of water (achieved by a Wangenstein apparatus) was applied, according to the method illustrated. Suction was continued until the cavity was reduced to very small size (5 c.c. or less).

The incidence of empyema was 9.7 per cent, or 30 cases. Five per cent of the bullet wounds, 10 per cent of the shell fragment wounds, and 66 per cent of the bayonet wounds developed empyema. The absence of any case of infection by the hemolytic streptococcus was thought to attest to the value of the use of sulfonamides. Organisms of the salmonella group were found in 3 cases. Four types of empyema are discussed:

1. Infection in a simple hemothorax—16 patients presented this type. They were managed by the principles outlined previously.

2. Infection in a clotted hemothorax (8 patients). These patients were managed in similar fashion, although the earlier the operation was performed the better the outcome. One case came to decortication. One patient with a cavity of 1,200 c.c. capacity, had suction applied 6 weeks after the original injury. In 17 days the cavity measured 50 c.c.

3. Putrid empyema, in 3 patients. These patients differed from those of Type I chiefly in the virulence of their infection. They were subjected to emergency operation and treated by airtight seal and suction.

4. Infected open sucking wounds, in 3 patients. In addition to the infection, these patients had disturbances in respiration. They were treated either by sealing the wound and providing drainage or by drainage through the wound, all of which was sealed.

There were no deaths among the 30 patients with empyema. Complete re-expansion of the lung was obtained in all but 2 patients. These had been treated conservatively, until recrudescence of fever brought about the demonstration of infection, presumably rupturing from the underlying lung into the hemothorax. The cavities were greatly reduced and both were closed by a Schede procedure.

There were 61 patients with retained missiles (7 bullets and 54 shell fragments). These did not seem important in the production of empyema. In no instance was it definitely demonstrated that the foreign body produced a typical putrid lung abscess, spontaneous drainage into the pleura was believed to have been seen, however. Only 1 patient had a massive pulmonary hemorrhage. Foreign bodies larger than from 1 to 1.5 cm. in size were generally removed; 23 of the 61 foreign bodies were removed. Two foreign bodies were associated with a putrid empyema in which operation was done as an emergency; 1 foreign body was removed from the pericardial sac because of effusion with tamponade and cardiac failure, 1 from the free pleural space because of persistent effusion, and 1 from the mediastinum, close to a large vessel, and 18 foreign bodies were removed from the lung more or less electively. The patients were allowed to recover as completely as possible from not only the lung wound but any pleural complication before removal was undertaken. The details of the operative approach are given. In 1 case a pure culture of *Clostridium welchii* was obtained from the cavity around the foreign body, but no complications occurred. No significant complications were encountered, and all of the patients returned to duty.

There were 4 patients who had recognizable wounds of the heart or pericardium. One had a perforation of his left ventricle, left lung and spleen. Although his wounds were repaired, he died. Another had a slow tamponade due to shell fragment lodged in the posterior pericardial sac. Two cases of pericarditis were seen following wounds. These 3 patients were successfully treated.

There were 46 thoracoabdominal wounds. The mortality in this group was 20 per cent, or 9 patients. Only 1 patient died as a result of a chest wound.

The total number of deaths in this series of 303 patients, regardless of the associated injuries or diseases, and regardless of the cause of death, was 21, a mortality of 7.4 per cent. Twelve of these patients had insignificant chest wounds. Only 6 patients, 1 per cent of the total series, died primarily of their chest wounds. The cause of death in these 6 was (1) a sucking wound that had persisted for 48 hours without treatment (the patient died 3 hours after being seen); (2) perforating wound of the heart, lung, and spleen; (3) cerebral air embolism (2 cases, 1 proved by autopsy); and (4) multiple lung abscesses (1 cases).

Numerous illustrative roentgenograms, as well as a photograph, are appended.

HIRAM T. LANDSTON, M.D.

Klosk, E., Bernstein, A., and Parsonnet, A. L.: Cystic Disease of the Lung. *Ann. Int. M.*, 1945, 24: 217.

Cystic disease of the lung is found in the course of routine physical and roentgen examinations since it rarely gives symptoms. The authors review the literature and report a series of 13 cases at the Beth Israel Hospital, Newark, New Jersey, discussing specifically the complications of this disease.

Cystic disease of the lung is defined as any condition in which the lung parenchyma is replaced by sharply defined cavities containing fluid or air. Dermoid cysts of the lung, echinococcus cysts, and encapsulated interlobar accumulations of fluid or air are excluded. Cystic disease may be congenital or acquired, or both, with the prevalent opinion leaning toward the congenital origin.

Clinically and pathologically, congenital cystic disease falls into two groups: (1) the large solitary cyst usually found in infancy and early childhood which displaces the heart and mediastinum and gives symptoms of cyanosis and dyspnea, and physical signs of tension pneumothorax; and (2) degeneration of the lung parenchyma by multiple millary cysts or large multilocular or unilocular cysts. Acquired pneumatocele or pneumocyst is usually associated with respiratory infection, chronic bronchitis or peribronchitis, pulmonary fibrosis, and emphysema or bronchial asthma.

The solitary cysts are lined by a layer of columnar and cuboidal epithelium resting on a tunica propria and a layer of connective tissue. The cavities in the cystic degeneration are similarly lined but the epithelium may be thrown into folds by intraluminal proliferation with an adenomatous appearance. Clusters of thin walled cavities communicating freely with the bronchi are lined with columnar ciliated or nonciliated epithelium. The contiguous alveolar walls in the presence of pneumatoceles or pneumocysts from bullous emphysema are encrusted with coal pigment.

Roentgenographically, an acquired pneumatocele may be indistinguishable from the congenital form, although one suspects the acquired form when the lesion is seen in an adult.

Röntgenographically, solitary cysts appear as large areas of radiolucency which may or may not contain fluid. They may be so ballooned out with highly positive intraluminal pressure as to resemble tension pneumothorax.

The second form of cystic disease is characterized by the honeycombed appearance of the pulmonary fields with thin walled, sharply defined annular shadows without accompanying interstitial parenchymal infiltration. Direct communication with the bronchus can be confirmed by bronchography on the finding of cystic spaces in grapelike clusters.

Complications of the disease are common and some of them bring the patient to the doctor. Upper respiratory infections are very often followed by infection in the cystic areas with episodes of pneumonia, without, however, the severe constitutional symptoms associated with acquired bronchiectasis, nor the cerebral manifestations associated with pulmonary suppuration. Cardiorespiratory reserve diminishes with age with increasing dyspnea and sometimes death from failure of the right side of the heart. The most frequent complication is hemorrhage, seldom profuse, but varying from slight hemoptysis to exsanguinating proportions; its true source has not been established.

The case reports describing the complications are given in the following order of frequency: (1) fluid filled cystic disease (1 case), (2) cystic disease complicated by hemorrhage (4 cases), (3) cases complicated by infection (2 cases), (4) cases complicated by spontaneous pneumothorax and hemopneumothorax (2 cases), and (5) acquired cystic disease (3 cases).

LYNN JOHNSEN, M.D.

Fattl, L., and Others: Acutely Infected Pleural Effusions; Techniques of Penicillin Treatment. *Lancet*, Lond., 1946, 1: 295.

The authors used various techniques in administering penicillin in the treatment of 24 acutely infected pleural effusions—in 14 while the pneumonic symptoms were still present and in 10 after this phase subsided. The success or failure of these techniques was determined by comparing the results with a series of 14 controls treated along well accepted lines. The duration of illness both from the earliest pneumonic symptoms and from drainage until full healing of the controls was 15 and 11.5 weeks, respectively. Any penicillin treated case taking as long as this full healing was considered a failure. Treatment was successful only when the duration was less than the shortest time taken by any of the controls—8.5 weeks from the earliest pneumonic symptom and 5 weeks from drainage.

Seven cases were treated by aspiration followed by the injection of penicillin. The organisms were the pneumococcus in 2 cases, the staphylococcus in 2, and the streptococcus in 3 cases. The results were success in 2 cases, partial success in 1 case, and failure in 4 cases. The successes occurred in cases with interlobar collections of not more than 2 ounces. One death occurred in this group. The failures oc-

curred in cases of extensive empyema in which the original thin fluid thickened so that aspiration was almost impossible. Three of these cases were treated later by rib resection. This method was abandoned early in the series except for small interlobar effusions which could be completely emptied by aspiration.

Three cases were treated by rib resection, all of which were considered failures as they healed in about the same time as the controls. Two cases were due to the hemolytic streptococcus and 1 was due to the anaerobic streptococcus. All 3 cases became secondarily infected with the staphylococcus aureus. This method of treatment was abandoned when it was realized how badly these cases were progressing compared with the others treated by the methods subsequently described.

Ten cases were treated by intercostal drainage and the instillation of penicillin with success in 7, partial success in 3, and failure in 1 case. There were 7 pneumococcal, 2 staphylococcal, and 1 anaerobic streptococcal cases. The intercostal tube was alternately used for drainage and the instillation of penicillin. The only failure resulted from faulty technique in draining a multiloculated empyema from one loculus only. Rib resection was eventually carried out. All these cases healed in from 6 to 7.5 weeks from the first symptoms and from 2 to 4.5 weeks from drainage. This method was most suitable for localized empyema, as the risk of lung collapse was slight and the emptying of the cavity was far more effective than aspiration once the exudate thickened.

Eight cases were treated by aspirations and injections, with subsequent intercostal drainage. There were 6 pneumococcal infections, 1 staphylococcal infection, and 1 pneumococcal infection, but no hemolytic streptococcal cases. Aspirations and injections were carried out for a preliminary period followed by an intercostal drain when the exudate thickened. These cases healed in from 5 to 8.5 weeks from the first symptoms and from 2 to 4.5 weeks from drainage. It was believed that the time of aspiration was unnecessarily prolonged in most cases. This is the method of choice for all effusions treated in the toxic phase because the lung expands readily and obliterates the cavity, and the fluid does not loculate.

In the treated series it was found that the intrapleural administration of penicillin not only influenced the local condition, but also provided a systemic concentration for periods of from 24 to 48 hours. The dose should be from 120,000 to 240,000 units for an adult and 1,000 units per pound of body weight per 24 hours for children under 5 years. Sterile cultures from pneumococcal and streptococcal effusions are by no means a reliable guide to the elimination of infection and time to stop treatment. Smears negative for gram-positive cocci are much more reliable. X-ray evidence save for fluid levels was not a safe criterion on which to rely for the discontinuance of drainage. Following surgical drainage, the risk of secondary infection was great and this prolonged suppuration and healing.

Fig. 1. Method of setting up intercostal drainage; (1) trocar and cannula inserted into the pleural cavity through a small incision through the skin and subcutaneous tissues; (2) mouth of cannula blocked with thumb till well fitting drainage tube is inserted while spigoted; (3) removal of cannula while air is prevented from entering pleural cavity by firmly gripping tube close to chest wall; (4) "elastoplast" cut to fit round and attach tube to chest wall; (5) second strip cut similarly; (6) third strip to hold the other 2 firm on tube. Tubes attached in this way have remained *in situ* 10 days in patients who were not restless.

Thin effusions in the toxemic phase should be treated by aspiration of as much fluid as possible, the last 10 c.c. being saved for bacteriologic examination. Penicillin, 240,000 units (2,000 units per pound of body weight in children under 5 years) in 20 c.c. of saline solution, should be injected slowly into the cavity and the patient must be watched for coughing up yellow stained sputum as this usually indicates a bronchopleural fistula. If the cultures are positive, the treatment is repeated every 2 days until the effusion is frankly purulent. Then an intercostal drain is inserted at the suitable spot—a trocar and cannula with a drainage tube which exactly fits the bore of the cannula (Fig. 1.) are used. The cavity is left to drain overnight under a water seal if the toxemic stage is passed. If not, an instillation of penicillin is given as soon as all the pus seems to be removed. Instillations are given twice a day in the tube with care to prevent the ingress of air. Up to 20 c.c. containing 500 units of penicillin per cubic centimeter are instilled, for pneumococcal or streptococcal infections if the toxemic phase is passed; 600,000 units are injected twice

daily for staphylococcal infections. Drainage is set up twice a day, an hour before each instillation, by connection with the under water system.

A roentgenogram is taken the day following the insertion of the drain to check on its position and to determine residual effusion. The film is taken after drainage and before instillation of the penicillin. Drainage and instillation are discontinued when the pus disappears and the discharge is serous or slightly turbid and watery. If 3 serial bacteriologic examinations made on separate days are negative for smear and cultures, the drainage tube is removed and a final instillation is made as it is withdrawn. A dry dressing is fixed in place over the sinus and is not disturbed for from 5 to 7 days, by which time the wound should be dry. If it remains wet it should be examined bacteriologically for secondary invaders of the sinus tract. Breathing exercises are instituted the day after drainage is started to aid in drainage and expansion of the lung. Washouts should be avoided unless the tube is clogged by fibrin. If necessary, washing should be done under aseptic precautions in the operating room.

If these procedures are followed, the period of aspiration and injection lasts about a week, drainage from 10 to 14 days, and full healing of the sinus another 7 to 10 days, a total treatment of from 4 to 6 weeks.

Purulent effusions are best drained immediately, before the fluid becomes too thick to pass readily down the intercostal tube.

Small cavities bounded by the interlobar space walls may be treated by aspiration and injection alone. Aspirations are carried out every other day and 240,000 units are injected. Indications for discontinuing treatment have been described.

The consensus of opinion is that aspiration and injection with penicillin, with or without intermuscular injections, may clear up empyema, but the pleural thickening and resultant diminished respiratory reserve following long persistence in this treatment cannot be overcome except by standard methods of surgical treatment. The authors demonstrate a technique which combines the use of an antibacterial agent and drainage, and causes minimal discomfort to the patient.

Although the standard for successful results was high, 18 of the 20 cases treated as recommended came up to it. The earlier the effusion was detected and penicillin started, the shorter the duration of the illness. There is good reason to believe that the duration of treatment will be even shorter when these cases are treated at the earliest possible moment that fluid is detected and referred early to the surgeon. Chronic empyema present a year or more will probably not respond to the treatment outlined here.

Aspiration was preferred to drainage because continuous retention of the drug was assured and contact of the drug with the whole infected area was secured. The patients, however, preferred the drainage, and the change-over was made as early as possible and in accord with good treatment.

Nine of the 24 patients had bronchopleural fistulas and in spite of this the treatment was effective. Injections given more frequently than once every 48 hours might be recommended, as the patients cough up a fair proportion of the drug.

When infections were not located, penicillin injected into the pleural space had a well marked effect on the toxic signs but failed to prevent the formation of pus.

The continual danger of superadded infection by gram-positive organisms, once the drainage had been set up, compelled the authors to continue with penicillin until no further interference with the wound was necessary. Rib resection offers a freer portal of entry to invading bacteria and prolongs healing. Superadded infection with gram-negative organisms is more of a nuisance than of serious consequence. It can be avoided by careful dressing.

The x-ray findings were a source of considerable concern to the clinician. In some cases drainage was prolonged, fruitless explorations performed after drainage had been discontinued, and rib resection and thoracoplasty were considered on the strength of residual shadows. Screening is an essential factor in the treatment of empyema to distinguish fluid from pleural shadows and to aid in placing the tube correctly.

ROBERT R. BIGELOW, M.D.

HEART AND PERICARDIUM

Levin, M. M.: The Clinical Picture and Therapy of Heart Injuries. *Vrachebnoe Delo*, 1945, p. 141.

In the majority of cases there is no clear cut picture of an injury of the heart. Especially during the first few hours of the trauma, signs considered typical for this type of injury, such as acute anemia and tamponade of the heart, are usually absent. In doubtful cases watchful waiting is indicated. The best approach is through the original wound which can be dilated by enlarging the port of entry and resecting portions of one or several ribs if necessary. Whenever possible the heart should be sutured *in situ*. The pericardium and pleura should be closed without drainage.

Early evacuation of the blood from the pleural cavity is important in the prophylactic treatment of infection as such blood may lead to a purulent pleurisy.

The remote results of suture of the heart may be quite satisfactory.

Subjective symptoms of an injury of the heart, such as anxiety, pain in the cardiac region, a sensation of oppression, weakness, dizziness, dyspnea, and fainting are present in not more than 50 per cent of the cases, and are of clinical importance only if combined with signs of progressing internal hemorrhage, acute anemia, compression of the heart, and a suggestive location of the external wound. Severe external hemorrhage is relatively rare because usually the blood first fills the pleural cavity.

The author prefers the approach through the original wound to methods employing musculo-

cutaneous or musculo-osseous flaps. In 1 case he was obliged to ligate the peripheral branch of the descending portion of the coronary artery. The operation was not followed by any immediate or remote untoward results. JOSEPH K. NARAT, M.D.

Finch, E.: Discussion on Surgery of the Patent Ductus Arteriosus. *Proc. R. Soc. M., Lond.*, 1946, 39: 107.

The chief danger in ligation of the patent ductus arteriosus is infection causing a subacute endocarditis which is fatal; but it is to be remembered that the patients with this condition, apart from being in danger from infection, must live the restricted life associated with a cardiac lesion. The diagnosis of the condition is not always an easy one. There are, however, some cardinal points in the uncomplicated case which may be mentioned. The patients usually are known to have had a cardiac lesion from childhood. They are usually small in size and they may complain of shortness of breath, but usually as they have had the lesion all their life, they are not conscious of this disability. On examination they have no finger clubbing and usually no cyanosis. Palpation over the pericardium may or may not reveal a turbulent heart action and a thrill over the upper part of the left chest, its maximum about the second interspace. Auscultation reveals the characteristic murmur suggesting a heavy machine shop and which is known as the "machinery murmur"; its essential feature is its continuous quality.

An x-ray film of the chest usually reveals certain characteristic features. The pulmonary artery is enlarged so that a bulge can be seen below the aortic knuckle, and there is usually some enlargement of the heart. The vascular shadows in the lungs are very obvious and in some cases markedly so.

Hunter believes that the mechanical defect, together with the risk to life, is sufficient to warrant surgical intervention in the uncomplicated case, except in that of the very young; in these cases operation should be postponed to a later date. A search for septic foci is made. Usually because of the cardiac condition patients have not had their tonsils and adenoids removed, but, when necessary, this is now a routine, the operation being performed under prophylactic doses of the sulfonamides. Breathing exercises are instituted as soon as the patients come into the hospital and are continued throughout their stay.

The operative technique employed by Hunter is the same in all cases and the approach used was that originally described by Gross. Although the approach is a limited one, it allows the reconstruction of the chest wall more completely and permits the re-expansion of the lung more easily than the thoracotomy incision. It does not allow, however, the same access in dealing with complications of the operation.

The ductus itself when defined is very short and runs an unexpected anteroposterior course. It can be elongated by gentle traction with a fine wire.

pulmonary artery while the ligatures are being passed. Two No. 8 silk ligatures are used as ties, care being taken not to damage the recurrent nerve with the ligatures.

The wall of the ductus itself varies in thickness. In the majority of cases it is very thin, and in 2 instances the author observed the blood moving in the vessel. In both of these the impression was given that the flow was from the pulmonary artery to the aorta. This is against all the views previously expressed, but these views have been largely theoretical. It has always been assumed that the flow was from the aorta to the pulmonary artery on the grounds that the pressure in the aorta was more than in the pulmonary artery and also that the enlargement of the heart suggested an extra load on the pulmonary side. This is further strengthened by the increased pulmonary vessel shadows as seen on x-ray examinations. It has been estimated that the flow through the ductus is very large, up to 50 percent or more of the left ventricular output. It is remarkable that this extra work does not result in more serious signs of myocardial insufficiency, and when the increase in blood pressure and the great increase in the size of the heart that occurs when an arteriovenous fistula of similar size is caused by injury is considered, one must ask if there is not some factor present in the congenital case that has not yet been explained.

Surgeons are not satisfied with ligation in continuity, and there is no doubt that the next forward step in this region is to divide the ductus completely.

The difficulties encountered during the operation are: the problems in connection with exposure, local bleeding of a slight character but sufficient to obscure the field and make the procedure tedious, puncture of the pericardial extension along the ductus with a small constant stream of pericardial fluid, the presence of glands in the arch of the aorta which are sometimes difficult to clear from the ductus, and, the most serious, the tearing of the ductus either while it is being defined or due to the ligature material cutting through it.

The complications after operation are fluid or air, or both, in the pleural cavity. In no case has there been cause for anxiety during convalescence, and by expanding the lung with positive pressure to reduce the air in the cavity there should be no danger. In an uncomplicated case there should be no blood in the pleural cavity.

The usual convalescence is quiet in children: they are well after 24 hours, and it is probably only conservatism that confines them to bed for a week or 10 days. The follow up shows that both the adults and children are more robust and in better general health than before. It would be fair to say that they were unaware until after the ligation of the ductus what limitations had been imposed on them because of their disability. In time the ultimate fate of these patients will be known. At this time it can only be said that by ligation of the ductus we have reduced their chances of getting a bacterial endocarditis.

In discussing this article *TUNAS* thought that Hunter's novel suggestion that the blood flow in a patent ductus during postnatal life was from the pulmonary artery into the aorta could not be maintained, although it provided a ready explanation for the surprising cure when infection was present. There appeared to be ample evidence in support of the classic view that the blood flow was from the aorta into the pulmonary artery: (1) in uncomplicated cases there was no cyanosis which could be present if venous blood were sucked into the aorta from the pulmonary artery; (2) the low diastolic pressure usually associated with patency of the ductus was readily explained by the classic view but very difficult to understand if the blood flow were in the reverse direction (the diastolic pressure was regarded as inversely proportionate to the calibre of the ductus); (3) pulmonary congestion due to the overloading of the pulmonary circulation from the aorta was often found several years before other signs of heart failure developed; (4) dilatation of the pulmonary artery sometimes with actual aneurysm formation (an x-ray film depicting such an aneurysm was shown) was commonly present because of the raised pressure caused by the flow from the aorta; (5) the oxygen content of blood removed from the pulmonary artery at operation had been shown to be abnormally high; (6) pulmonary infarction always preceded systemic embolism when subacute endarteritis had complicated the picture; and (7) there was the irrefutable evidence of cardioangiography, revealing that none of the relatively concentrated dye in the pulmonary artery entered the aorta.

The indications for surgical closure of the ductus required careful consideration. Infection was undoubtedly an absolute and urgent indication for operation as the prognosis in unoperated cases had been almost universally fatal in the past. Symptoms or signs of cardiac failure were regarded as indications for operation. In addition, enlargement of the heart or a diastolic pressure below 60 was thought to foreshadow failure at a later date and was therefore grounds for surgical treatment. Retarded development in childhood was likewise an indication.

Preparation for operation in the uncomplicated case was not thought necessary. If infection was present a sulfonamide was given for 5 days before operation in order to reduce the fever. If it failed to do so, penicillin was given for a similar period and with the same object. An intravenous drip was started before operation in case of severe accidental hemorrhage, but was discontinued as soon as the operation was completed as the burden on the heart would be augmented by the infusion of fluids in the absence of blood loss.

In isolation of the ductus, it is important to recognize a fingerlike process of serous pericardium which often overlaps the anterior part of the pulmonary end of the ductus. This process should not be opened but should be stripped off the ductus toward the heart by blunt dissection. If it is opened, the constant leak of pericardial fluid will obscure the field.

Patience and gentleness are the passwords to success in the rest of the process of isolation.

The means whereby permanent closure of the ductus might be invariably obtained is the most outstanding problem. In view of the reports of successful cases which were treated by division between clamps, this should be considered in many, if not all, cases.

STEPHEN A. ZIEMAN, M.D.

Sellors, T. H.: Constrictive Pericarditis. *Brit. J. Surg.*, 1946, 33: 215.

Surgical intervention in disorders of the human heart is still regarded as something in the nature of a dramatic adventure, although in recent years it has been shown that the surgeon's hand is more kindly tolerated than was once thought possible.

Constrictive pericarditis which ties down the heart movement and produces chronic compression can be relieved only by some direct form of excision of the cicatrized pericardium.

The essence of constrictive pericarditis lies in the fact that contraction of pathologically formed intrapericardial adhesions restricts the normal action of the heart. It is well known that adhesions can exist without obvious interference with function: on the other hand, extrapericardial adhesions dragging on a diseased heart may add to its enlargement.

Starting then with a constricting and limiting layer of dense fibrosis in the pericardial tissues it is possible to see how increasing contraction brings about progressive impairment of cardiac function. The heart is practically strangled to death by cicatrization of its own movement.

The chief effect of the fibrosis is to limit diastole. The oncoming venous blood cannot be accepted in full amount by the restricted relaxation, and the pump, being insufficiently supplied, has less to deliver in its forcing stroke.

On the arterial side of the circulation, the limitation of the diastolic supply and consequent reduction of the systolic output is recognized by a low level systolic blood pressure (from 90 to 110 mm. Hg) and a low pulse pressure (from 15 to 25 mm. Hg not being unusual). In normal circumstances the response to exercise results in an increased output of the heart beat associated with some increase in rate, factors which combine to give a substantial increase in the volume output per minute. In constrictive pericarditis the output per beat is limited and the only way in which the necessary volume per minute can be sustained is by an undue increase in the pulse rate. Tachycardia is therefore a comparatively early sign and this becomes even more prominent on exertion. Dyspnea similarly occurs on exercise, but is absent at rest, and does not occur when the patient is lying flat (an important sign in the differential diagnosis). The presence of a paradoxical pulse is common.

Edema occurs in the dependent parts of the body, particularly in the legs, where in course of time the edema takes on a lymphatic appearance. Facial and arm edema may be present although they are not

always noticeable, but swelling of the face has been seen to develop in the course of days when rapid constriction was occurring. Cyanosis of varying degree is common and the extremities are blue, cold, and uncomfortable. These symptoms are out of proportion to the degree of dyspnea, being more dependent on the raised venous pressure than on the unduly reduced cardiac output.

Liver enlargement with ascites is one of the cardinal signs of constrictive pericarditis: both are proportionally much greater than in a comparable case of congestive heart failure. Apart from other significant signs the enlarged belly is almost bound to attract attention.

A remarkable feature in all this interference with the circulatory system is that the lungs are unaffected.

Such symptoms as lassitude, wasting, and weakness are regularly encountered and can be understood in the light of the general interference with the circulation.

To complete the classic triad of the compression syndrome, according to Beck, a small quiet heart should be added. This, however, requires qualification, since a reduction in the apparent size is by no means always seen, but the presence of a 'quiet' or practically immobile heart can be emphasized.

One of the fundamental points of constrictive pericarditis is that the heart muscle is normal in nearly every case. The myocardium is not diseased and it is potentially sound, although its activity has been sorely restricted in the process of constriction. If the restraining pericardium is removed, in the course of time the myocardium will be able to function with a power that approaches normal. Moreover, the condition only embarrasses the patient's existence when the local mechanical state has jeopardized the circulation as a whole.

Whereas the heart muscle itself is relatively normal, the same cannot be said about cardiac rhythm. The presence of contracting scar tissue and even plaques of calcium around the "pacemaking" area may account for irregular stimulation. All types of irregularity are encountered and periodic changes of rhythm are not uncommon. Operative handling of the heart produces extrasystoles and sometimes fibrillation, although these disturbances, even if they are more than transitory, generally subside within 24 hours. Any pre-existing irregularity is not necessarily replaced by normal rhythm after surgical removal of the pericardium, although this has occurred on occasions.

Electrocardiography shows remarkably uniform results, the principal features being a low voltage type of curve and lowering or inversion of the T-wave. The loss or inversion of the T-wave is commonly seen in Leads I and II and contrasts with pericardial effusions, which exaggerate the RS-T and the T-wave. After pericardiectomy there is some improvement in the voltage and a tendency for the T-wave to become less flat or inverted, but this is not marked for some time after effective liberation of the heart.

The current literature submits three possible causes for the origin of constriction—*tuberculous* infection, old pyogenic pericarditis, and idiopathic factors. The last accounts for the largest group in the published records, but it is easy to understand that the limited tissue available for microscopic examination from pericardial excision, and the duration of the disease fail to afford complete facilities for investigation.

The future of a patient with constrictive pericarditis depends on the rate of development of the condition. The slowly developing case which is not submitted to careful and systematic investigation may pass through many hands before the disease is finally diagnosed. These patients can live for years in limited and tolerable health.

Removal of the restraining pericardium to allow as full a ventricular expansion as possible is the only treatment for established pericardial constriction. Excision of all the pathological pericardial tissues would be the ideal; however, this is not practicable but the improvement following limited removal is remarkable. Excision should aim primarily, and possibly only, at freeing the ventricles, although for anatomic reasons even this is rarely achieved. The usual procedure is to resect the anteriorly placed pericardium and to carry the dissection outward over the apex and around the left border of the heart. The very thinness of the auricles and great veins makes interference over them a hazardous undertaking. Attempts to perform an extensive ventricular clearance without an opening into the left pleural sac often results in a more limited operation than was originally planned. To free the left border of the heart to an adequate extent the dissection should be carried posteriorly beyond the line of the phrenic nerve; but to do this and at the same time preserve the integrity of the pleural cavity is practically impossible. Consequently a deliberate transpleural approach to the heart may be countenanced as readily as the more popular extrapleural exposure.

The incision through the pericardium should be carried through both layers down to the heart muscle and not only through the parietal layer. This must be emphasized because it is quite easy to find a plane of cleavage between the parietal and visceral pericardium even after years of apparent adherence. The dissection plane between the visceral pericardium and myocardium is not as easy to define.

The full aim of dissection is to free the anterior surface of the right ventricle and the front part of its diaphragmatic aspect, and to free the left border of the heart from over the apex well on to the diaphragm and complete the excision laterally behind the level of the left phrenic nerve. The obliquely placed auriculoventricular groove marks the upper limit, and although clearance beyond this area is frequently advocated, it can be seen from a section of this region that there is little margin for error.

The tolerance of the heart muscle to handling is considerable. The ventricles respond to manipulation by repeated extrasystoles and are liable to

fibrillate if touched too often and too much; consequently periods of rest should be a routine part of the operation. During these intervals small warm packs or muscle grafts can be applied to bleeding areas on the freed heart muscle. The possibility of cardiac arrest is present, but with the heart practically under manual control this need not be too alarming; 5 cc. of 1 per cent procaine injected intravenously is sufficient of value in controlling an unduly turbulent heart.

STEPHEN A. ZIEMAS, M.D.

ESOPHAGUS AND MEDIASTINUM

Patterson, C. O., and Rouse, M. O.: Esophageal Varices. *J. Am. M. Ass.*, 1946, 130: 334

Esophageal varices on direct inspection through the esophagoscope are so large in some instances that they softly occlude the esophagus.

Patients have complained that substernal and upper abdominal distress precedes hematemesis, and it is possible for the patient and the patient's family to predict the approaching catastrophe of hemorrhage. It appears, therefore, that persistent substernal distress occurring in a patient having known or suspected esophageal varices would indicate the need for x-ray study and probably esophagoscopy as well as the injection of any veins large enough to produce symptoms.

The authors have noted that patients in a critical state of shock immediately before the injection, appeared in no danger at all a few moments after the injection, and were sitting upright in bed sipping milk 10 hours later. It would thus appear safe to give the injection treatment after the patient is in the proper hospital environment with reasonable assurance as to the diagnosis and with adequate facilities, particularly typed whole blood, available. The contraindications to esophagoscopy should, of course, always be kept in mind.

In the instance of another patient, the preparation for necessary splenectomy was repeatedly disrupted by massive hematemesis. Only after the injection of the sclerosing solution into the esophageal varices did the hematemesis cease and the red blood cell count maintain a safe level for surgery.

Hemorrhage occurs not infrequently from esophageal varices. This fact, as Kegaries showed, is best explained by the anatomy of the gastric veins, which tend to be subserosal and are held more firmly by the less elastic structure of the stomach. On the other hand, in the esophagus the varicose veins tend to be submucosal and are held less firmly by the areolar tissues of the esophagus; therefore they have a tendency toward saccululation and protrusion into the lumen of the esophagus, where they are more vulnerable to ulceration and rupture.

The ultimate evaluation of the treatment of esophageal varices by the injection of sclerosing solutions will take some little time and careful observation.

Five per cent sodium morrhuate solution was used for the injections.

JOHN J. STATOVSKY, M.D.

Montaño, G.: Clinical and Roentgenological Aspects of the Differential Diagnosis of Mediastinal Tumors (Consideraciones clínicas y radiológicas en relación con el diagnóstico diferencial de los tumores del mediastino). *Gac. méd. México*, 1945, 75: 277.

Since mediastinal pathology and especially that of mediastinal tumor is a very difficult one from the diagnostic standpoint, a study of it based on 80 cases seen in the Cancer Section of the General Hospital of Mexico City is presented.

The anatomy of the mediastinum and of its contained structures is reviewed. The author divides the mediastinum into an anterior and a posterior portion by a vertical plane passing through the pulmonary hilum, and into an inferior, middle, and superior section.

Symptoms produced by mediastinal tumors are essentially due to pressure or encroachment on, or displacement of, the adjacent organs by the process. These lesions may reach huge proportions without symptoms or may, by their relation to juxtaposed organs, produce definite localizing signs. Three general classes of symptoms are to be recognized: (1) respiratory or digestive symptoms, (2) symptoms due to the involvement of the nervous system, and (3) symptoms due to the involvement of the vascular tree. The first group of symptoms is very much as expected. The second group is also of understandable manifestations, although localization by the segments of the peripheral nerves involved may be helpful, or the discovery of a Horner's syndrome or recurrent laryngeal nerve palsy is quite diagnostic. In the third group, it will be remembered that the establishment of collateral circulation may indicate, for example, whether the superior vena cava is involved above or at the confluence of the azygos vein. The collateral channels are thoracic if the involvement is above the juncture, and abdominal as well as thoracic if both vessels are involved.

Of the 80 cases studied, 60 were manifestations of lymphoblastoma. The symptoms in order of frequency were dyspnea, supraclavicular or cervical thickening or tumefaction, pain, cough, edema, cyanosis, a collateral venous circulation, and hemorrhage.

The malignant mediastinal tumors, in general, do not produce the extensive compression or displacement syndromes that benign neoplasms do because they tend to invade rather than compress or displace, and their course is rapid, not allowing time for the development of a compensatory mechanism.

The roentgenological approach to the study of the mediastinum is also difficult because of the superimposition of the shadows produced by the several organs contained within it. Demonstration of abnormality depends on the encroachment of the process onto the space occupied by the lung field.

The first question to settle is whether the abnormal x-ray shadow is primarily in the lung or in the mediastinum. This can be inferred by observing the

angle of incidence of the shadow with the mediastinal border (according to Lenk). Oblique projections of the thorax will be useful in determining whether the mediastinal lesion is anterior or posterior.

Malignancy is suggested by irregular borders of the shadow, which indicate invasiveness. The degree of displacement or compression of the adjacent organs is important, in that benign tumors are more apt to present this feature in greater degree than infiltrative malignant ones. A symmetrical tumor suggests a single origin in contradistinction to a lobulated one; the latter suggests a multicentric character such as occurs in tumors of the lymphatic group.

Finally, irradiation can serve as a basis for classification of these tumors by the type of response produced. Great radiosensitivity indicates tumors of the lymphoblastoma group. Within this group certain variations permit distinctions, for example, between Hodgkin's disease and the more radiosensitive types. Moderate response is seen in carcinomas of the thymus or thyroid, fibrosarcoma, and metastatic carcinoma. No response suggests a histologically benign neoplasm, or aortic aneurysm.

The location of the tumor offers some differential help: it is in the anterior mediastinum, one should suspect cysts, teratomas, intrathoracic goiters, tumors of the thymus, or aortic aneurysms; but if it is in the posterior mediastinum, one should expect tumors of neurogenic origin, vertebral tumors, cold abscesses, lymphatic tumors, or aneurysms of the descending aorta.

Numerous illustrative roentgenograms are appended, without case histories.

HIRAM T. LANGSTON, M.D.

Adams, W. E.: Surgery of the Mediastinum. *Surg. Clin. N. America*, 1946, 26: 130.

During the past three decades, with their advances in the control of surgical pneumothorax, exposure of the mediastinal structures has become possible and treatment of congenital lesions, infections, tumors, cysts, or traumatic lesions has advanced apace. The scope of surgery in this region is now extensive. The details of 3 cases illustrating the more common procedures are given.

The first case was that of a 45 year old, white woman with a dermoid cyst of the mediastinum. She came under observation because of an intrathoracic mass discovered by a routine employment roentgenography as the condition was virtually asymptomatic. Her general condition was excellent, positive findings being confined to the chest. The roentgenogram revealed a huge rounded mass some 14 cm. in diameter in the right lower anterior lung field. Normal diaphragmatic motion was present and no expansile pulsation could be made out fluoroscopically. No calcification could be seen in the mass.

Thoracotomy was performed through a right anterolateral incision. The pleura was entered through the sixth interspace and additional exposure

was secured by dividing the fourth, fifth, and sixth cartilages and extending the incision in this line. The mass was easily removed after incision of the mediastinal pleura. The lung expanded freely. The thorax was closed with drainage. The postoperative course was uneventful and the patient was discharged at 2½ weeks. She was asymptomatic 11 months after the operation. The specimen was a cystic mass containing yellow fluid, cheesy material, and hair. The wall, microscopically, revealed stratified squamous epithelium, hair follicles, and sebaceous glands.

Mediastinal dermoids are usually located anteriorly and produce symptoms largely because of their size. They may undergo malignant change and for this reason their removal is indicated.

The second case was that of an 18 year old white male with a neurogenic tumor of the mediastinum. He presented a mass in the upper right chest adjacent to the mediastinum. It measured from 2 to 2½ inches and was relatively asymptomatic. It was found on a routine chest roentgenogram. The mass did not pulsate on fluoroscopic examination. No other abnormality was discovered. Under general anesthesia the right pleural cavity was entered through the bed of the sixth rib. This tumor presumably arose from an intercostal nerve and was found lying along the vertebrae opposite the third, fourth, and fifth ribs. After removal, the raw area was covered by pleura and the chest closed in layers, catheter drainage being provided. The postoperative course was uneventful and the patient was asymptomatic when seen 6 months later. The mass weighed 58 gm. and was considered a neurofibroma after histological study.

The mediastinal tumors of nervous tissue origin are usually located posteriorly. They are frequently asymptomatic, but they undergo malignant change and may produce symptoms by pressure on the adjacent structures. They are to be differentiated from cysts, intrathoracic goiter, and aneurysm.

The third case was that of a 55 year old white male with carcinoma of the esophagus, who complained of difficulty in swallowing for 9 or 10 months. This was first noted with solid food, later with liquids also, and during the last 2 or 3 months a tendency to regurgitate food was noted. Pain in the epigastrium, particularly when he was trying to swallow solid food, had been noted for this period also. He had lost 35 pounds in weight and a great deal of strength. He was markedly dehydrated and emaciated. A pronounced esophageal obstruction at the junction of the middle and lower thirds of the esophagus was demonstrated by barium study.

After 10 days of preparation, operation was undertaken. The left pleural cavity was entered through the bed of the eighth rib and the incision extended upward after resection of short segments of the fifth, sixth, and seventh ribs posteriorly and ligation of the corresponding intercostal vessels. The lesion extended from just below the aortic arch downward for some 4 inches. The mediastinal pleura was incised and the esophagus mobilized. The right

pleural cavity was not opened. The diaphragm was then opened and the stomach mobilized. The left gastric artery was ligated, but the gastroepiploic artery along the greater curvature was preserved. The spleen was removed to facilitate the procedure. The esophagus was transected at its lower end and the cardia closed by a double row of sutures. The esophageal mobilization permitted delivery of the tumor above the aortic arch. The stomach was brought up into the chest and anchored to the parietal pleura. The esophagus was anastomosed to an opening in the fundus of the stomach by a double row of sutures. Careful protection against solz was taken and rubber shod clamps were used during the procedure. The diaphragm was closed around the stomach. Sulfathiazole crystals were placed about the anastomosis. The chest was closed in layers with drainage.

The procedure was performed without shock and convalescence was uneventful. The patient was allowed to drink small amounts of water on the fifth day, and by the twelfth day had progressed to 6 soft feedings a day and fluids as desired. He was discharged in 3 weeks and was still well after 8 months. The tumor was a squamous cell carcinoma confined to the esophagus. The diagnosis was made by barium study and esophagoscopy.

Great progress has been made in the surgical management of these lesions. Operation offers the only chance for survival in these patients and the risk is not formidable.

Sketches, roentgenograms, and photographs of the specimen accompany the discussion.

IRVING T. LAXGROV, M.D.

MISCELLANEOUS

Svet, N. M.: The Pathogenesis, Clinical Picture, and Therapy of Chest Injuries. *Vrachebnoe Delo*, 1945, p. 135.

The author reports on 2,500 cases of chest injuries, 45.2 per cent of these wounds had a port of entry and exit, while 45.8 per cent were blind. Among the early complications, shock was observed in 0.6 per cent, acute hemorrhage in 2.3 per cent, and aerobic infection in 0.5 per cent. Among late complications the following are mentioned: empyema in 16.8 per cent, pleurosepsis in 2 per cent, infiltration of the lungs in 10.7 per cent, pulmonary abscess in 5.6 per cent, gangrene of the lungs in 0.3 per cent, pneumonia in 6.3 per cent, exacerbation of tuberculosis in 0.5 per cent, and toxic psychosis in 0.5 per cent.

In 54.3 per cent of the patients with hemorrhage the latter disappeared nearly completely, leaving in a small number of cases adhesences which yielded to diathermy, iodoiontophoresis, and other methods of physiotherapy. In 18.8 per cent hemothorax and hemopneumothorax became transformed into a pyothorax, which in 2 per cent had an acute course in the form of pleurosepsis. Sixty-five per cent of the infiltrations were absorbed while in 35 per cent of the

cases an abscess developed. Of the secondary lobar pneumonias, 60 per cent were located at the site of the injury and 40 per cent on the opposite side. Contrary to the common pulmonary abscess which produces a characteristic roentgenogram, the traumatic abscess of the lungs may not show air above the fluid level. The latter spreads in concentric direction while the common abscess of the lung spreads in an eccentric direction.

The empyema complicating a hemothorax is usually unilocular while that complicating a hemopneumothorax is multilocular.

The following therapeutic measures were used by the author: (1) active therapy of the hemorrhages; (2) Bulau's drainage, instituted early and continued for a short time; (3) stimulation of the absorption of infiltrations and abscesses; (4) general stimulation of the organism in the form of blood transfusions, intravenous administration of glucose, employment of cardiac stimulants, vitamin C, and good nourishment; and (5) early employment of physiotherapy in order to prevent pneumonia and diminish anoxemia.

Aspiration of the hemothorax was usually started on the day following the injury. A rib resection was performed only for empyema of long duration or any other virulent process. As a rule, the drain was introduced in the ninth intercostal space in the posterior axillary line. A drain was never introduced into the port of entry of the missile.

In cases with empyema the pleural cavity was irrigated with potassium permanganate, hydrogen peroxide, chloramine, streptocide, rivanol, or alcoholic solution. Patients with abscesses or infiltrations of the lungs were given, in addition to other therapeutic measures, intravenous injections of sodium benzoate, rivanol, saline solution, calcium chloride, sodium salicylates, or novarsenol. The best results were obtained from intravenous injections of from 10 to 15 c.c. of a 10 to 15 per cent sodium benzoate solution given daily over a period of 10 days.

Iodoform in the form of an emulsion proved efficient in the treatment of gangrene of the lung.

Repeated blood transfusions up to 10 were given to patients with complications.

Patients with an open pyothorax were treated with Bulau's drainage and occlusive dressings after a preliminary introduction of Vishnevski's ointment into the pleural cavity.

In open hemothorax the gravity of the condition soon after the injury is attributable not to mediastinal flutter but to pleuropulmonary shock. Therefore, the advisability of transforming an open pneumothorax into a closed one is sometimes open to discussion.

Graded breathing exercises were instituted in all patients with penetrating chest injuries; they were started on the day following the trauma, in order to prevent pneumonia and anoxemia. The exercises were not employed in the presence of repeated hemorrhages, shock, or anaerobic infection. In patients with multiple rib fractures paravertebral block

with novocain was employed to diminish pain which would interfere with the breathing exercises.

Thirty-five patients, or 14 per cent, died. The mortality in empyema was 2.4 per cent, in lung abscess 2.1 per cent, in traumatic pneumonia 2.5 per cent, in pleurosepsis 24 per cent, in acute hemorrhage 28.5 per cent, in gas infection 16.5 per cent, and in shock 6.6 per cent.

Forty-seven and two-tenths per cent of all the patients with chest injuries recovered within 30 days after the injury, 23.9 per cent within 50 days, and 29.9 per cent within 60 days.

Foreign bodies in blind injuries usually became encapsulated.

If a chest injury is combined with a transdiaphragmatic trauma of the abdomen, either a typical or a transdiaphragmatic laparotomy is indicated.

JOSEPH K. NARAT, M.D.

Samson, P. C., Burford, T. H., Brewer, L. A., III, and Burbank, B.: The Management of War Wounds of the Chest in a Base Center. *J. Thorac. Surg.*, 1946, 15: 1.

This article encompasses the experiences of the first fully established center for thoracic surgery in the north African theater of operations receiving its patients from the Sicilian Campaign. The principles of treatment delineated are the outgrowth of an overall experience with some 1,500 major thoracic injuries. The trends of therapy are illustrated by reports of representative problem cases amply supported by roentgenograms and sketches.

Blood was found in the pleura in virtually all intrathoracic injuries. Treatment was by means of thoracentesis without air replacement, beginning after 3 or 4 days (during which time cessation of the pulmonary bleeding or leakage of air was expected, by virtue of the partial compression), unless the symptoms demanded earlier aspiration. Air replacement was believed to defeat the purpose of obliterating the pleural space by pulmonary re-expansion. Fever was frequently present, but generally subsided in a few days in the absence of infection.

The intrapleural blood frequently clotted; it may do this within a few hours. If the hemothorax was not reducible by thoracentesis, catheter suction also failed to provide significant improvement.

Clotting of the hemothorax is frequently followed by organization, although the factors responsible for this are not clear. Within a week fibroblastic and angioblastic proliferation may be seen extending from the pleura into the overlying fibrin coat. In 4 weeks, adult fibrous tissue can be recognized in the older layers, and in 6 or 7 weeks, the organized layer may be 1 cm. thick. The parietal portion is invariably thicker than the visceral. This is erroneously called "thickened pleura." The lung is encased in this cicatricial envelope, being thereby compressed and immobilized. Infection does not alter the process of organization, that element being manifested by leucocytic infiltration in the unorganized zone of the fibrin clot primarily.

The first application of the principle of decortication in this theater was by one of the authors (T. H. B.), in May, 1943. This operation is indicated when at least 50 per cent compression of the lung is present, especially if the apex is collapsed; and in those in whom aspiration has been unsuccessful and in whom there has been no appreciable pulmonary expansion at the end of 4 to 6 weeks following injury.

The optimum time for such intervention is between 3 and 5 weeks following injury. "The important technical considerations are: (1) meticulous establishment of the proper cleavage plane between peel and visceral pleura; (2) careful blunt dissection of the peel either digitally or by gauze dissector; (3) complete freeing of the lung where it is directly adherent to the thoracic wall, to the mediastinum, or along the fissural margins, so that circumferential expansion can be obtained; (4) decortication and mobilization of the elevated fixed diaphragm, with particular attention to redeveloping the costophrenic sulcus; (5) deliberate intermittent expansion of the lung under increasing positive pressure, with careful stroking of atelectatic areas." After decortication, a grossly normal, thin, translucent expansile pleura is found. Bleeding is only moderate and easily controlled by pulmonary expansion. Decortication of the parietal "peel" is not considered necessary.

Proof of infection in these cases was based on finding organisms in the bloody fluid aspirated from patients showing clinical signs of toxicity. There was frequently a delay in obtaining bacteriologic confirmation. Anaerobic streptococci and staphylococci were frequent offenders.

Small empyemas have been treated by the usual methods of aspiration and drainage, but larger ones (with 25% or more pulmonary compression) have been managed by evacuation of all clot and decortication of the parietal peel. This has been done under the protection of systemic and local administration of the sulfonamides or penicillin. The mechanism of production of post-traumatic empyema varies, since contamination may enter through the chest wall, from the lung by way of a bronchopleural fistula, or by spillage from an abdominal source when the diaphragm is involved. The latter type may occur as a result of contamination in a pleural space relatively free from blood and do well under the usual methods of drainage. Nearly every post-traumatic empyema, however, develops in a hemothorax (hemothoracic empyema) and the infection is contained within the walls of the intrapleural hematoma instead of being confined by the pleurae themselves. In these cases total empyemas are more frequent, and pulmonary expansion is more often problematical, as compared to postpneumonic empyemas, and periosteal reaction and clubbing of the fingers are not seen. Adequate drainage is necessary and can be promptly carried out without awaiting "thick pus," since the fear of mediastinal mobility is not great in view of the pathogenesis of the condition. Water seals are not mandatory after drainage. If pulmonary expansion does not occur in from 4 to 6 weeks,

decortication has given gratifying results. Decortication without preliminary drainage in patients in good condition is feasible and recommended.

Multiple empyema, particularly in the presence of bronchopleural fistulas, in an otherwise expanded lung, is best managed by accurately placed multiple rib resections, as indicated.

Because of the cloth and debris in the wound, foreign bodies (metallic from 1.5 cm. up in size) should probably be removed, preferably between the fourth and tenth days after injury. This allows the lung to recover from its original trauma and be readily expansile, yet not lay down dense pleural adhesions or heavy fibrosis around the missile. Most of the pericardial and myocardial foreign bodies should probably be removed. However, removal of retained fragments that are asymptomatic is a problem *sub judice*.

Continued intrapleural bleeding generally comes from some vessel in the chest wall. Severe hemorrhage has rarely been seen from a lung wound.

The 15 detailed case abstracts illustrate the diagnostic approaches, principles of management, operative details, and immediate end results. Thirty-two illustrative roentgenograms and 4 sketches are included.

IRIAM T. LANGSTON, M.D.

Keynes, G.: The Surgery of the Thymus Gland
Brit. J. Surg., 1946, 33: 201.

Up to a recent date there has been almost complete absence of surgical interest in the thymus gland. In support of this statement the author points out that there has never before been a contribution on this subject in the *British Journal of Surgery*.

Surgery of the thymus principally includes operations for the relief of thymic asthma, tumors, and myasthenia gravis. Thymic asthma is sometimes seen in young children in whom there is a recurrent difficulty in breathing associated with stridor and cyanosis. Death sometimes ensues. The asthma has been supposed to be due to the pressure in the thorax of an abnormally large thymus, and attempts have therefore been made to relieve the supposed obstruction to respiration by removing the thymus. It was claimed that in four-fifths of the operated children the attacks of suffocation ceased, and stridor was less.

Surgical therapy, however, was shortlived and medical opinion has fluctuated as to whether the thymus gland is really the cause of thymic asthma. It is no longer generally believed that the thymus is the cause of death in the so-called "status lymphaticus." But apart from this there was another good reason why surgery for this condition has lapsed out and has not been heard of for many years. An enlarged thymus gland consisting largely of lymphoid cells can be made to disappear rapidly under x-ray irradiation.

Thymic tumors are common. Lymphosarcoma, teratoma, Hodgkin's disease, spindle-cell sarcoma, and epithelioma have been described, but

their removal has seldom been attempted, and most of those that have been removed were in patients who had myasthenia gravis associated with the growth.

It seems that of the five kinds of thymic tumor the epithelial tumor is the only one that is ever found coexisting with myasthenia gravis and, furthermore, when the epithelial tumor occurs, the association with myasthenia is almost invariable.

Blalock's recent success with the relief of myasthenia gravis by thymectomy directed attention to this field of surgery, and since 1942 Keynes has performed 51 such operations. The technique employed consists in a T-shaped incision over the sternum and the latter is divided with a Schumacker's sternum splitter as far as the fourth cartilage.

Exposure of the mediastinum permits dissection of both lobes of the gland and their removal. On removal of the retraction the two halves of the sternum spring back into their proper position and the soft tissues over them are securely sutured in two layers with strong catgut. The cancellous bone heals rapidly and care is taken not to limit the maximum

excursion of the chest in any way by tight bandaging.

The association of a thymic tumor with myasthenia gravis has an important bearing on the treatment of myasthenia by thymectomy, which is often unsuspected. It seems that at least 1 in 10 of the patients coming to operation is found to have a tumor, and the implications of this fact are of considerable importance. The tumors are thickly encapsulated, but, nevertheless, they show a tendency to burst through the capsule, and histologically they consist of a homogeneous mass of epithelial cells in a state of great activity. Their appearance suggests that the margin between innocence and malignancy is rather fine, and the removal of these tumors at as early a stage as possible is of the greatest importance to the patient's welfare.

All patients with tumors tend to respond more slowly and incompletely than most individuals respond to prostigmine.

Of the 51 patients whom Keynes operated on, 38 are still alive and have been benefited by the operation.

STEPHEN A. ZIEMAN, M.D.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Hobbs, W. H., and Cohen, S. E.: *Gastroduodenal Invagination Due to a Submucous Lipoma of the Stomach*. *Am. J. Surg.*, 1946, 71: 505.

The authors present a complete classification of the forms of intussusception which occur in the alimentary tract. They then present a case report of a gastroenteric type of intussusception seen in 1937.

The patient, a 61 year old white female, was troubled with constipation for 12 years. Three years before admission she began to lose weight and tired easily. In November, 1935 she had a severe paroxysm of pain in the right upper quadrant of the abdomen radiating to the back and right shoulder. It was accompanied by nausea and vomiting. She was treated medically for gall bladder disease and recovered, but had many similar milder episodes. In December, 1937 she was unable to retain food in her stomach, had mild pain, and vomited for 3 days before admission. Bowel movements were normal. For a year previously, she had noted a nontender mass above the umbilicus.

Physical examination revealed dehydration, a soft abdomen, and a freely movable (3 by 5 cm.) mass in the epigastrium in the region of the transverse colon. The admission diagnosis was carcinoma of the trans-

verse colon with metastatic obstruction of the pylorus. Gastrointestinal x-rays revealed that the antrum of the stomach did not fill and there was marked retention (50% after 48 hours). Laboratory examinations showed a moderate anemia. On the fifth day in the hospital the patient developed severe generalized abdominal pain with rigidity and tenderness.

Laparotomy was performed on the ninth day. At least two-thirds of the stomach with the greater part of the omentum had become invaginated into the duodenum (Fig. 2). The latter was dilated up to 3 inches in width. A tumor mass measuring about 4 by 3 inches in diameter was palpable at the duodenojejunal junction. By slight traction on the cardia and a milking manipulation, retrograde disinvagination was effected. The circulation of all bowel was found to be unaffected. After reduction a large intragastric tumor was palpated. The anterior wall of the stomach was opened and a large pedunculated soft tumor was found attached to the posterior wall by a broad short pedicle.

A sleeve resection was carried out because the nature of the tumor was uncertain. A cholecystectomy was done as the gall bladder contained numerous calculi. The patient made an uneventful recovery, regained 20 pounds of weight, and has been

Fig. 1. The anatomic relationships encountered during the laparotomy.

invagination with an external mechanism to distinguish it from the usual intussusception displaying the internal mechanism. These classifications are suggested by the authors after a study and review of the 41 cases presented in the literature.

According to this nomenclature the authors' case presented was complete, central, of grade IV, and with an internal mechanism. Only 2 other cases reported were of this type; 9 were more severe; 7 were of grade II; and 4 were of grade III. The central type is more frequent than the lateral, and the complete more common than the partial.

The symptoms at the onset are those of a benign stomach tumor—pain in the epigastrium or umbilical region, nausea, vomiting, eructations, anorexia, fatigue, diarrhea, loss of weight, and emaciation. Hemorrhage and melena are frequent and at times a tumor is palpable. If the papilla of Vater is occluded, jaundice may occur. In a late stage the picture is one of intestinal obstruction requiring an emergency operation. Grades I and II may lead to a ball-valve syndrome with a sudden obstruction of the pyloric lumen by a relapsed tumor or intussusception. The symptoms are sudden with violent attacks of retching and vomiting accompanied by flatulence and pain. These attacks subside in time, and the patient is comparatively well between attacks.

Roentgenologically, in these cases Moore's criteria for the diagnosis of a benign gastric tumor are in part applicable. In addition, (1) a central area of translucency in the bulb with moderate transitory foreshortening of the antrum with a shift of the pylorus to the left may occur; (2) converging axial striations are caused by tension on the cardiac portion of the stomach; and (3) parallel transverse striations perpendicular to the axial striations are due to barium in the lumen of the intussusceptions. Other cases show the "abrupt sign"—abrupt delineation of the media running across the middle of the stomach, with or without spurs.

Natural cures of intestinal polyps following torsion and strangulation of the pedicle have been reported. Surgical excision of the offending tumor by local or sleeve resections is the usual procedure. The latter is preferred when intussusception is present. The prognosis is defined by the degree of prostration, the severity of the bowel damage, and the patient's ability to withstand the operation.

The lesions occur when there is a morbid feature, such as a tumor of the stomach or a mucosal tumefaction. Certain predisposing factors such as mobility of the pyloric or cardiac end of the stomach with relaxed gastrohepatic and gastrocolic ligaments usually are present. The tumor acts as a foreign body within the lumen and excites the gut to expel the tumor. Peristalsis carries it into the succeeding bowel segment, and the tumor pulls the stomach after it.

The mode of development of gastroduodenal invagination with an external mechanism is different. The stomach glides isoperistaltically and surrounds

the first portion of the duodenum. Fixation of the aboral bowel segment is an absolute requirement.

Two cases of double invagination involving the stomach are reported. ROBERT R. BIGELOW, MD

Delannoy, É., and Verhaeghe, M.: Ulcers Located High Up on the Posterior Surface of the Stomach (Ulçères haut situés de la face postérieure de l'estomac). *Rev. chir.,* Par., 1945, 64: 193

The diagnosis and treatment of ulcers located near the cardia are always difficult, but especially when such ulcers develop on the posterior surface of the stomach. This type of ulcer is rare as evidenced by the fact that the 4 cases here reported were the only ones encountered in a series of 1,500 gastrectomies. No instances of ulcer involving the tuberosity above the horizontal line passing through the cardia were encountered. This type is also extremely rare, occurring in less than 3 per cent of all gastric ulcers. The incidence of ulcer of the subcardiacity at the junction of the upper and middle third of the vertical portion of the stomach has been variously cited as from 6 to 17 per cent. Such ulcers are often of considerable size and have a tendency to come to a head at the upper margin or tail of the pancreas or to become adherent to the posterior abdominal wall. Spontaneous healing is probably not infrequent.

In gastrectomies for ulcer, heavy bands are frequently encountered, fixing the anterior surface of the pancreas to the posterior surface of the stomach. The pain is not of constant type, but in one case spontaneous subcostal pain or subcostal pain, induced by the method of Mallet-Guy for diagnosis of chronic pancreatitis, could be demonstrated. An earlier x-ray examination had yielded negative results, but a later film taken with this possibility in mind yielded positive results. The pain has also been known to simulate that of phrenic origin or of angina pectoris. The clinical symptoms are vague and of little diagnostic aid.

Roentgenographic examination by ordinary techniques usually yields negative results. The ulcer, even if it has had time to become visible, and is located in the middle of the posterior surface, will not change the appearance of the two curvatures. According to Moutier, these ulcers can be more easily demonstrated gastroscopically. Ledoux-Lebard and García Calderon have recommended a special technique for roentgen visualization of these ulcers. By following the descent of the first swallow of the contrast medium, a small hook of esophageal medium may be demonstrated at the site of the ulcer, but this is a transitory phenomenon and might also be caused by a fold of the gastric mucosa. Ascending palpation following the ingestion of the contrast medium may likewise be employed to produce a suspended ulcer image. The best method consists of examination of the patient in dorsal decubitus after ingestion of sufficient contrast medium to fill the tuberosity. The posterior surface, having become inferior in this position, can then be examined as the

air forces back the anterior surface which has become uppermost. A combination of careful clinical, radiological and gastroscopic study will yield the best diagnostic information.

Various surgical methods have been recommended to deal with high posterior gastric ulcer. The technique of Pauchet, which has been found useful for high ulcer of the lesser curvature, will not suffice. In ulcers of the upper third of the posterior surface of the vertical portion of the stomach, a total subcardial gastrectomy may be necessary. In most ulcers of the subtuberosity, subtotal gastrectomy is indicated, although in very small ulcers the section may be made obliquely from above downward, proceeding from the ulcer toward the greater curvature. This approximates Pauchet's "section en gouttière", and facilitates gastrojejunal anastomosis. Such interventions as transpyloric gastrectomy, wide gastroenterostomy, Madlener's operation, and total gastrectomy should be reserved for special indications. Transpyloric gastrectomy is recommended only for anemic, aged, or debilitated patients. Also Madlener's operation should be attempted only in aged or debilitated patients or in cases of constricted thorax with little prospect of tolerating a longer more difficult intervention. Good results were obtained by gastrectomy in all of the 4 cases treated by the authors.

EDITH SCHANCHE MOORE.

Krarup, N. B.: On the Results of the Medical Treatment of Peptic Ulcer. *Acta med. scand.*, 1946, 123: 181.

In an effort to elucidate the results obtained by medical treatment of peptic ulcer, the author studied 665 patients (449 men and 216 women) admitted to Bispebjerg Hospital, Copenhagen, in the period from 1931 to 1938. All had uncomplicated cases of peptic ulcer, which were classified as bleeding (165 cases of hematemesis and 122 of melena) and nonbleeding or painful (81 gastric and 297 duodenal ulcers, all roentgenologically demonstrable) ulcers.

Patients with bleeding ulcers were given a puree diet throughout their hospital stay; those with gastric or duodenal ulcers were started on milk and strained oatmeal and allowed additions until they too were on a puree diet. Both types of patients were kept in bed for 3 weeks. After about 4 weeks they were discharged but advised to continue the dietary regime at home for at least four months. The follow-up study consisted of detailed questionnaires.

The immediate results of treatment were good. Ninety-five per cent of patients with bleeding ulcers were symptom-free at the time of discharge from the hospital. Five per cent of these had a relapse very soon after discharge. Of the patients with painful ulcers, 75 per cent of those with gastric ulcer and 80 per cent of those with duodenal ulcer felt well at the time of discharge. Of these patients, 20 per cent had a relapse almost immediately after leaving the hospital. Final results, after an observation period of at least 5 years, were less encouraging. Of the 626 patients who could be located, 29 per cent had

recovered, 36 per cent were improved, and 35 per cent had a poor result. The first two categories include patients who had suffered relapses; the last category includes those who died, i.e., 15 per cent of the total number of patients.

In analyzing the factors related to the disease, the author points out that age and sex seem to have little bearing on the outcome. The duration of the disease had a definite bearing on its outcome. Patients who had had ulcer for less than 6 months had a 50 per cent chance for recovery. This figure decreased to 20 per cent as the duration progressed to 3 years. A previous cure of the disease decreased the patient's chance for recovery. Results of treatment were poorest in patients with duodenal ulcers and best in those with bleeding ulcers. Fifty-eight patients were subjected to operation, 17 of them for perforation. The other 41, most of whom had duodenal ulcers, sought relief from symptoms. Relapses were frequent. The greatest number occurred in patients with gastric ulcers, 86 per cent of which recurred. Only 3 per cent of the group of patients died as a direct result of having an ulcer. Nine died of perforation, 8 of hemorrhage alone, and 2 of pyloric stenosis.

A comparison of the author's material with studies made by Nielsen and Mattisson showed that peptic ulcer has not undergone any essential changes as a disease, although it has undergone considerable change in its manifestations within the past 25 years. From being a disease chiefly involving the corpus ventriculi and encountered especially in women, it has now become a disease seen chiefly in man and most often involving the duodenum. Therapeutic results for the now predominant duodenal ulcer appear to be even poorer than would be expected from previous investigations.

The author's concluding opinion is that since medical treatment has effected such poor results for a steadily increasing number of duodenal ulcers and for recurring gastric ulcers, whereas resection appears to be producing an increasing number of cures, the indications for surgery should be broadened.

B. F. LOUNSBURY, M. D.

Rickles, J. A.: Multiple Carcinomas of the Stomach. *Surgery*, 1946, 19: 229.

The occurrence of multiple benign lesions of the stomach has been reported several times, and, although multiple malignancies of the gastrointestinal tract are second in frequency to skin lesions, multiple malignancies of the stomach are comparatively rare. A case in which 5 primary cancerous lesions of the stomach were present, and which was treated by transthoracic gastrectomy, is presented. The patient was a negro male, 54 years of age. Following preliminary study a diagnosis of carcinoma of the stomach was made. Abdominal exploration was performed and a large carcinoma of the cardia which had extended into the thoracic esophagus was found. The stomach was opened to permit examination and biopsy of a small, soft lesion at the pylorus and was

then closed, following which it was mobilized for a second stage transthoracic removal. Three weeks later a total transthoracic gastrectomy was performed with a good recovery.

Pathological study of the specimen showed ulcerating carcinoma of the cardiac end of the stomach infiltrating the muscularis, with metastases to the perigastric lymph nodes, and four papillary adenocarcinomas of the gastric mucosa apparently arising from adenomatous polypi. These tumors involved the mucosa and submucosa, but not the muscularis. Although much alike microscopically, these tumors were separated by normal mucosa and submucosa. The patient died suddenly several months later after a sudden onset of distention, which may have been due to metastases. **JOHN L. LUNDEQUIST, M.D.**

Norgaard, F.: Periodic, Spontaneously Remittent Volvulus and the Symptoms in Cases of Colon Elongatum. *Acta radiol.*, Stockh., 1945, 26, 163.

The term volvulus usually calls to mind an acute intestinal obstruction and consequent local circulatory disturbance due to a loop of bowel turning about its mesentery (pathological volvulus). The author reminds us, however, that lesser turnings of intestinal loops have long been known to occur without producing symptoms (physiological volvulus), and he records 4 cases which at roentgen examination of the colon with a barium enema were believed to have low grade asymptomatic volvulus of a redundant sigmoid loop and demonstrated an accompanying long axial torsion of the involved bowel. In such cases the volvulus and the consequent torsion at each end appeared not to exceed 180 degrees, so that no obstruction was offered to the passage of contrast material.

It is pointed out that while a volvulus of 180 degrees does not cause actual obstruction, it may result in a considerable obstipation and pain if the axial torsion be forcibly compressed into a shorter portion of the twisted loop or adjacent segment, as may occur secondary to increased dilatation of the loop. The author has encountered 4 cases in which the patients gave a long history of frequent attacks of sudden abdominal pain associated with obstipation. In 3 of these relief was customarily obtained by change of position (lying down) and followed by a sudden passage of much flatus, and in each a barium enema revealed this type of volvulus without ileus but with localized axial torsion in a redundant sigmoid (3 cases) or a long loop of the transverse colon (1 case). In each instance slight to marked resistance was offered to passage of the barium column at the point of the compressed torsion. Operation was performed in 2 cases, and in each the mesentery of the sigmoid loop was found to be scarred. Resection of the involved loop was done in 1 case, while in the other the loop was derotated and fixed. Following operation both patients had relief of the periodic attacks of pain. The author believes that these 4 cases represent instances of periodic, spontaneously remittent volvulus, which in the

fourth and most severe case had ultimately become unable to twist spontaneously because of the marked scarring of the mesentery.

In addition, the author presents 8 other patients complaining of attacks of obstipation, meteorism and vague abdominal distress, in whom low grade volvulus and axial torsions were found at roentgen examination. In most of these instances there was some obstruction to the passage of the barium column until the bowel became derotated.

LILIAN DONALDSON, M.D.

Hunt, C. J.: Early Diagnosis and Management of Small Intestinal Obstruction. *Surgery*, 1945, 19: 237.

The purpose of this article is to emphasize the possibility of small intestinal obstruction when abdominal colic not localized to any quadrant or specific viscus in the abdomen occurs. Small bowel obstructions may be divided into the external, on the surface of the abdomen, and those hidden within the abdominal cavity. Those on the surface of the abdomen are strangulated obstructions and are easily diagnosed. The obstructions within the abdomen are hidden from sight and the diagnosis is often delayed, which results in serious complications. The intra-abdominal obstruction of the small bowel may be a simple form of obstruction in which the visibility of the bowel is not in jeopardy, or it may be a strangulated or volvulus type in which the blood supply is obstructed and gangrene is imminent. In the former, delay is not so serious as in the latter. Thus, the surgeon is faced with two problems in obstruction of the small bowel: first, a clear distinction must be made as to the probable nature of the obstruction; second, the integrity of the blood supply to the bowel must be considered.

There are some points of diagnostic importance which will aid in arriving at an accurate conclusion. In simple obstruction, rigidity and localized tenderness are not present. When localized tenderness and rigidity are present in small bowel obstruction, it may be stated that a strangulated loop of bowel is present and the blood supply is in danger. The absence of early physical signs suggests the possibility of bowel obstruction. Passage of gas or movement of the bowels does not eliminate the possibility of obstruction. The typical transverse pattern visualized on x-ray examination is not necessary for a diagnosis of small bowel obstruction. Collection of gas in the small bowel of an adult may be considered as synonymous with obstruction, but in very small children gas may be seen in the small bowel and be of no diagnostic significance. Gas in the bowel and be of no diagnostic significance. Gas appears early after the onset of obstruction and is usually demonstrable within a few hours. The distribution of gas in the small intestine is indicative of the probable type of lesion. In simple obstruction it may be centrally located, with a transverse loop may assume no definite pattern and proximal bowel distention is slow in developing. If the walls separating

the loops are thick, it signifies the presence of fluid or exudate. Gas may be demonstrated long before distention and the transverse x-ray pattern appears. In postoperative distention there may be a question as to whether a mechanical obstruction or paralytic ileus is present. In the former event, the small intestines are distended, while in the latter there is distention of both the small and large bowel.

The simple adhesive obstructions are the most common types involving the small intestine, and their presence can be detected early by roentgenographic study. Loop obstruction presents an entirely different roentgenographic pattern and a distinct surgical urgency because of impending bowel gangrene. Small bowel obstructions frequently occur in association with inflammatory lesions within the abdomen and usually present the characteristic pattern of a progressive proximal bowel distention in which the viability of the bowel is not in jeopardy. In this type of obstruction it is often not necessary to interfere surgically, as the condition results from localized inflammation and edema which will usually subside. Surgery is attended by great danger to the inflamed edematous bowel and may lead to extension of the infection. Intestinal decompression by intubation and appropriate systemic measures will usually result in recovery. Mesenteric thrombosis is characterized by acute sudden pain and gaseous distribution in the small intestine. Intrinsic lesions obstructing the small bowel are due to the occasional obstruction from a gall stone or incomplete obstruction from a neoplasm. In partial obstructions much difficulty may be experienced in making a diagnosis from the roentgenographic film unless intermittent complete obstruction is present. The use of an opaque medium is an aid to diagnosis in these cases. Any retardation of the barium in its progress through the intestinal tract or the detection of a malformed loop is of great significance. The diagnostic and therapeutic value of the x-ray in intussusception is discussed.

The use of the Miller-Abbott tube is contraindicated as a preoperative measure in loop obstruction, volvulus, or in strangulated obstruction when the viability of the bowel is in jeopardy. It may be employed to advantage in selected cases of intestinal obstruction. The technique of the passage of the tube is described.

An analysis of a series of 41 operative cases of obstruction of the small intestine in which there were only 3 deaths is presented.

JOHN L. LINDQUIST, M.D.

Barney, C. O., Roettig, L. C., and Jones, G. F.: Mechanical Intestinal Obstruction following War Wounds of the Abdomen. *Med. Clin. N. America*, 1946, 30: 337.

The authors state that never before have so many soldiers sustained abdominal wounds and survived to return to civilian life, and never before have so many young adults suffered injuries to, and under-

gone multiple celiotomies on, their peritoneal cavities. As a result, intestinal obstruction due to adhesions is being encountered with increasing frequency. Mechanical obstruction as a result of abdominal wounds of either the liver or the small bowel was encountered in 1 of every 18.5 cases on the Surgical Service at Rhoads General Hospital, Utica, New York, during the past year. The incidence of obstruction of the small bowel was 3.5 times greater than that of obstruction of the large bowel.

In obstruction of the small bowel, all manner of kinks, torsion, and internal herniations may be encountered. The most common forms are the "fixed kink," the "closed loop," or the "double fixed kink," and the "traction obstruction" with an adhesive band at the apex of a loop of gut acting as an axis about which a volvulus can take place.

In colonic obstruction, the most common finding is an inadequate lumen, often resulting from a Mikulicz type of colostomy closure.

The authors do not await such advanced signs as "the stepladder effect" on either inspection or x-ray examination, nor do they await fecal vomiting. The most common symptoms in obstruction of the small bowel are the onset of increasingly severe intermittent crampy abdominal pains accompanied by nausea, and usually by vomiting. Unless perforation has already resulted or is imminent, marked abdominal rigidity is usually not present. Auscultation of the abdomen is most important. At the onset of obstruction, violent intestinal peristalsis can be heard. Later the abdomen is more quiet and the cracked bell sound is heard. In the roentgen examination, the stepladder effect should not be used as a criterion. The visible distention of an isolated loop or loops of small bowel indicates an obstruction which usually requires surgical intervention.

In large bowel obstruction, the symptoms develop more slowly and are more mild in character. The patient complains of mild abdominal cramps, particularly after meals, abdominal fullness, and often nausea. A history of closure of a colostomy is important. No relief will be obtained with enemas, since the rectum is usually empty. A skiodan enema is of value in localizing the exact point of obstruction, after a flat plate has shown marked distention of the colon proximal to the point of obstruction.

The authors believe that prolonged observation has very little or no part in the treatment of complete mechanical intestinal obstruction following abdominal war wounds. They believe that an early celiotomy offers the most satisfactory means of removing the cause of obstruction and saving the patient's life. Although it is admitted that the Miller-Abbott tube is of definite value in the treatment of inhibition ileus and in incomplete small bowel mechanical obstruction, the authors are opposed to its use in complete obstruction following abdominal war wounds.

In the authors' experience with obstruction following abdominal war wounds, the incidence of strangulation or marked interference of blood supply is far

greater than the usual 10 per cent figure. This is one reason why they are not in favor of the routine use of a Miller-Abbott tube. As soon as the diagnosis is checked by means of positive physical findings and x-ray evidence of a distended loop, Wangensteen duodenal drainage is started. Estimation and correction of the fluid and electrolyte balance are carried out as rapidly as possible. A celiotomy is then performed without further delay. All possible raw surfaces are peritonealized after the strangulated areas are released. When too extensive damage to a loop is noted, resection and anastomosis are done. Postoperatively, Wangensteen suction is continued for at least 48 hours. Penicillin and sulfadiazine are given in adequate amounts. Prostigmine in 1:2000 strength is administered for at least 5 to 7 days postoperatively, starting with one ampule every 3 hours from the first day and gradually decreasing the dosage. Fluid and electrolyte balance are maintained and amino acids and vitamins are administered.

In the treatment of complete obstruction of the colon, it is usually possible to do a primary resection and an end-to-end anastomosis by an aseptic technique. Occasionally it is possible to straighten out an angulation or correct a narrowing of the lumen by longitudinal incision of the bowel and transverse closure. When colonic obstruction is not quite complete, it is often possible to delay operation sufficiently long to administer sullasuxidine and sullaganidine preoperatively. In the authors' series, none of the patients treated in this manner have had an unsuccessful result or postoperative peritoneal infection.

HAROLD LAUFMAN, M.D.

Bottin, J.: Communication between the Duodenum and the Pancreas (Communication entre le duodenum et la pancréas). *Rev. belge sc. med.*, 1943, 14: 13.

The question of a communication between the pancreatic ducts and the bile ducts has gained great importance in the pathogenesis of pancreatic necrosis. A number of experimental and clinical studies have demonstrated a reflux from the duodenum toward the bile and the pancreatic ducts. Pancreatic necrosis has been caused by the migration of parasites from the duodenum into the pancreatic duct, by obstruction of the pancreatic duct by a grain of oat and, in rare cases, by a melon pit. It has been suggested that most of the cases of acute pancreatic necrosis originate from a lesion of the pancreas which causes paralytic duodenal obstruction with paralysis of the sphincter of Oddi, and this in turn allows a reflux of duodenal secretion into the pancreatic duct.

The author reports a series of experimental studies on the dog:

X-ray study. A duodenal obstruction was produced in the dog and was followed by the injection of an opaque solution of sodium iodide into the duodenum. Roentgenograms taken the day after and repeated daily were unsuccessful in demonstrating a reflux toward the pancreatic duct.

Bacteriologic study. Aseptic removal and culture of small portions of the head of the pancreas of the dog almost always yield bacteria of the streptococcus or bacillus perfringens group. A similar excision from the dogs with duodenal obstruction yielded, in addition, the bacillus coli, enterococcus, bacillus tetragenus, bacillus putrificus, and at times, even the bacillus tetani. Since these bacteria are frequently found in the intestine of the dog, a reflux from the duodenum toward the pancreatic duct appears likely.

Enzymatic study. Trypsin occurs in the pancreas in an inactive form. A piece from the duodenal portion of the pancreas of a healthy dog exhibits a very low tryptic activity upon gelatin, graded by index 4. Pancreatic tissue from a dog with duodenal obstruction shows a highly increased tryptic activity, between 1,024 and 5,000. This is probably due to activation of the pancreatic enzymes by a reflux of duodenal kinase. It is unlikely that the kinase has reached the pancreas by the blood stream, because such increased tryptic activity is almost limited to the duodenal portion of the pancreas, and because the remarkable degree of activation observed does not compare with the activation obtainable by blood.

Section of the pancreatic ducts. If the main and accessory pancreatic ducts were cut from 3 to 4 mm from the duodenal wall and left open, the animal suffered no damage, and an exploratory laparotomy after from 24 to 96 hours showed only a thin peritoneal exudation, due to pancreatic juice which had escaped from the cut ends of the ducts. There was no trace of tissue necrosis. If, on the other hand, the duodenum was obstructed at the same time, the animals succumbed from 48 to 96 hours after the operation. The autopsy revealed necrotic foci in the pancreas, fatty necrosis of the mesentery, and, at times, a diffuse peritonitis. This indicates an activation of pancreatic enzymes by a reflux of kinase from the obstructed duodenum through the cut distal stumps of the pancreatic ducts.

The author concludes that in certain cases of high intestinal obstruction a reflux takes place from the duodenum toward the pancreas.

ARTHUR J. LESSER, M.D.

Larsen, S. B.: Some Cases of Intestinal Tuberculosis in Phthisics, with Reference Especially to the Prognosis. *Acta radiol.*, Stockholm, 1945, 26: 117.

The author reports his x-ray findings in 32 cases of intestinal tuberculosis assumed to be secondary to known and proved pulmonary tuberculosis. Histological proof of intestinal tuberculosis was established in 3 cases. All cases were examined by means of the oral administration of barium. The diagnostic x-ray criteria were: hypermotility in 23 cases, filling defects in 32 defects, ileostasis in 15 cases and a positive Stierlin's sign—absence of barium in the affected section of the cecum and ascending colon, while barium is present above and below it—in 1 case. The lesions seemed to be confined to the cecum

and ascending colon in 28 cases, but appeared to extend into the ileum in 4 cases.

All of the cases were treated with total body carbon arc light baths and 1 case also with x-rays. Twenty-one cases were followed up by further x-ray examinations. These subsequent examinations were entirely negative in only 3 cases.

GERHART S. SCHWARZ, M.D.

Gray, H. K., and Sharpe, W. S.: Gastric Retention after Posterior Gastroenterostomy for Duodenal Ulcer; Prevention and Treatment. *Ann. Surg.*, 1946, 123: 397.

A comparative study was made of two groups of consecutive cases of 100 each in which posterior gastroenterostomy for duodenal ulcer was performed. The factors of age, sex, activity of lesion, position of stoma, and technical skill were fairly constant. Because of the high incidence of post-operative retention in group 1, changes in the technique of operation and of postoperative care were made in caring for the patients in group 2 in order to combat postoperative gastrojejunitis, to promote peristalsis, and to avoid overloading the stomach. These changes consisted of the use of three rows of sutures instead of two, as well as the postoperative regulation of fluid intake and the administration of medications such as tablets of aluminum hydroxide gel (creamalin tablets), neostigmine (prostigmine methylsulfate), phenobarbital (luminal), atropine, diphenyl acetic acid, and diethylaminoethanol (transentol).

A comparison of the two groups revealed that the average incidence of retention of any degree decreased from 35 per cent in group 1 to 19 per cent in group 2 and the average incidence of serious retention (persisting longer than 5 days) decreased from 24 to 13 per cent. In the first group 6 patients were subjected to a secondary operation; in the second group there was no necessity for reoperation.

There is no single cause of postoperative gastric retention, so there can be no single remedy. The temperament, racial characteristics, and emotional stability of the patient, as well as his economic and social stresses, are important. The size and position of the stoma, operative technique, and the pre-operative and postoperative care are similarly important.

Regurgitant vomiting is of two general types: (1) the vomiting that develops immediately after operation, which suggests mechanical obstruction, and (2) the vomiting that develops between the sixth and tenth days after operation, which occurs most probably because of stomal edema and inflammation. For the first type, some further operative procedure is frequently necessary; for the second type, supportive measures involving a knowledge of the principles of blood chemistry and fluid balance are usually sufficient.

Each surgeon should adopt an operative technique and a program of preoperative and postoperative care that embody the principles which in his

hands give good results. In the authors' experience, the stoma is best made on the posterior wall of the stomach with the proximal loop of the jejunum attached near the lesser curvature at the level of the angle of the stomach. The stoma is made to run diagonally downward and to the patient's left toward the greater curvature. Three rows of suture should be used in the anastomosis, the third row solely to allow careful approximation of the mucosal edges and to cover all denuded portions. The distal loop should be carefully replaced in the abdominal cavity to lie behind all other loops of bowel. If a secondary operation is considered, jejunostomy alone is the procedure of choice and is usually all that is necessary.

Crook, E. A.: Nonspecific Intestinal Granuloma. *Proc. R. Soc. M., Lond.*, 1946, 39: 123.

In reporting 5 cases of intestinal granuloma or regional ileitis, Crook emphasized the varied clinical picture which this condition may assume. Severe hemorrhage was the chief symptom in 2 instances and fistula in 2 others, while abdominal pain associated with a tumor mass was the predominant complaint of the fifth patient.

The cause of the disturbance was obscured in each case and operative treatment failed to arrest the pathological process. The histologic appearance of the tissues and the liability of the disturbance to recur after operation seemed to point to an infection as the causative agent, the true nature of which was undiscovered. The topic was enlarged upon by Manson-Bahr, who emphasized that the pathological process can be divided into various stages:

Stage of acute suppuration. The affected length of the bowel is dark red in color and greatly thickened and there are usually yellow shreds of fibrin adherent to the inner mucosa. The nearby glands are enlarged and red in color. There is free, sometimes turbid, fluid in the peritoneal cavity. Miliary abscesses sometimes found in the submucosa resemble those seen in full blown phlegmonous gastritis.

Chronic stage. Descriptions of this stage are commonly found in the literature. The appearance of the affected bowel to the naked eye is typical and corresponds to Dalziel's simile of an "eel in a state of rigor mortis," or it is more commonly referred to as the "hosepipe appearance." The serous surface of the bowel has a grayish pink color with white, thickened patches representing organized fibrin. The terminal portions of the affected loop are often affixed to the pelvic brim by recent adhesions.

The fibrostenotic stage. In this stage the cellular structure has largely been replaced by fibroblasts which have laid down collagen fibers, and these have produced marked narrowing of the area. It is this stenosis which gives rise to the roentgenographic "string sign of Kantor." As this constriction advances, the blood and lymphatic supplies of the bowel are interfered with and widespread ulceration of the mucosa takes place.

Fistula formation. As originally pointed out by Crohn, there is a marked tendency toward the formation of fistula and this may precede even the initial symptoms. These fistulas sometime travel a long distance before they reach the surface. It has been suggested that they may be of chemical origin, due to the action of the intestinal juices or possibly to the virus of lymphogranuloma inguinale.

In the discussion of the etiology it was stated that the chronic stages of Crohn's disease have certain resemblances to tuberculosis of the hyperplastic type, but no subserous tubercles have ever been demonstrated. The general form of the lesions in the large bowel, when these are encountered, bears a resemblance to the intestinal phenomena of lymphogranuloma. Moreover, phlegmonous enteritis has the same pathological picture as that of Crohn's disease and its resemblance to phlegmonous gastritis has already been observed. From a correlated study, positive cultures of bacillus dysenteriae, Flexner and Sonne, were obtained during the acute and positive agglutination tests in the chronic stages, which indicated a dysentery association. It has been suggested that chronic ileitis might be related to sarcoidosis. With this object in view, a skin lesion from a proved case of sarcoidosis was emulsified; this gave positive intradermal reactions in 2 cases of sarcoidosis and also in 2 cases of regional ileitis.

By the injection of various sclerosing agents into the mesenterics and subserosal lymphatic channels and the introduction of bacteria intravenously at the same time, edema and extensive infiltration of the bowel wall can be produced; this suggests a low grade lymphatic infection. However, this has been interpreted as showing that disease of the mesenteric glands might be primary and that the ileitis might be due to the lymphatic block. Moreover, a streptococcus of the enterogenous type may be isolated from the floor of the ulcers as well as from the peritoneal fluid. If the bacterial nature of the disease is accepted we must be prepared to explain the mode of entry. The ulceration might well prove the site of entry of the primary infection. Trauma such as fish bones may be the cause.

At present, histological study remains the only safe means of identifying the lesion, which appeared to be the result of hyperplasia of the lymphoreticular tissue leading to obstructive lymphedema. The lymphadenoid masses vary in size, the largest forming cellular aggregates from 3 to 4 mm. in diameter and being visible to the naked eye. The smallest are 0.4 mm. in diameter and microscopic in size. In three-quarters of the cases these cellular nodes are scattered evenly throughout the edematous mucosa, ranging from 8 to 18 to the square centimeter. They show considerable cellular activity, a characteristic cellular response in a variable number of germinal centers making up a nodule of lymphadenoid tissue. The affected germinal center is later replaced by proliferating endothelial cells with weakly staining nuclei. In the midst of the cells constituting endothelial aggregates it is usually possible to find a

Langhans' giant cell which, when mature, resembles the giant cell system of miliary tuberculosis, but when this system has reached its full development, all proliferation apparently ceases. Never has the slightest evidence of caseation been seen. Some of the cells contain crystalline masses of various shapes and sizes. Probably the most arresting histologic feature is the presence in the regional lymph nodes of a clear cut specific formation of giant cell systems identical with those of the thickened mucosa. The natural retrogression of this lesion can best be studied in this situation. When viewed as an isolated and static histologic picture, the giant cell systems, both in the glands and the bowel, are indistinguishable from those of tuberculosis, but the absence of caseation and of acid fast bacilli force one to doubt their tuberculous origin.

From the purely histologic aspect, the appearance, evolution, and retrogression of the giant cell system of Crohn's disease resembles more the tissue reaction of Boeck's sarcoidosis than tubercle infection.

STEPHEN A. ZIMAN, M.D.

Atwood, W. G.: Meckel's Diverticulum. *N. Eng. Land. J. M.*, 1946, 234: 320.

Meckel's diverticulum is found in from 2 to 3 per cent of all autopsies, and about 3 times as often in males as in females. It is usually found from 50 to 45 cm. proximal to the ileocecal valve, but it may occur at any point between the pylorus and the ileocecal valve, usually arising opposite the attachment of the mesentery. Intestinal obstruction caused by a diverticulum is very rare; it may be caused by an obliterated omphalomesenteric duct forming a fibrous band constricting the bowel, or the diverticulum itself may cause constriction if its tip is attached to some point in the peritoneal cavity, or if the diverticulum is very long. The diverticulum may also invaginate itself and start intussusception; this is frequently facilitated by a polyp present in the diverticulum, or else a free diverticulum may be inverted as a whole.

Thirty-seven cases of Meckel's diverticulum have been recorded at the Truesdale Hospital in 69,000 admissions; only 1 case of intussusception as a result of inversion of the diverticulum was observed;

A case of a 7 year old boy is reported; he had complained of severe abdominal pain, nausea, and vomiting 2 days prior to admission. On admission the patient was cyanotic, and his general condition was extremely poor with a temperature of 100.6°F., pulse 130, respirations 22, labored; the abdomen was markedly distended, tympanitic, and tender, and no peristalsis was heard. Urinalysis showed a trace of albumin, hyaline casts, and pus cells; the hemoglobin was 80 per cent, the red blood count was 4,440,000, and the white blood count was 14,650 per cent neutrophils, 20 per cent lymphocytes, 2 per cent large mononuclear leucocytes, 8 per cent band forms, and 2 per cent metamyelocytes. The patient was very restless on admission, and was given 1,000 c.c. of 5 per cent glucose in saline

Fig. 1.

solution by rectal clysis prior to surgery. Under nitrous oxide, oxygen, and ether anesthesia, the abdomen was opened through a right rectus incision. A considerable amount of foul smelling fluid was encountered in the abdominal cavity and the small intestine was markedly distended. The terminal ileum was found to be prolapsed into the cecum through the ileocecal valve, as shown in Figure 1 a. Figure 1 b explains the mechanism of intussusception. The intussusception was reduced and an inverted Meckel's diverticulum was found at the apex (1 c). In spite of supportive measures, such as oxygen and intravenous fluids, the patient died an hour after operation. Permission for an autopsy could not be obtained.

The authors stress the need of early diagnosis and surgery in these cases, while the patient is still a good risk; they also recommend the search for a Meckel's diverticulum at every laparotomy.

ARTHUR J. LESSER, M.D.

Dixon, C. F., and Benson, R. E.: External Fecal Fistulas. *J. Am. M. Ass.*, 1946, 130: 755.

Early operation for the elimination of external fecal fistulas is usually not advisable.

Many fistulas close spontaneously with conservative, nonsurgical treatment.

In the early, acute stages of the formation of fecal fistula, treatment consists in transnasal intestinal suction, warm applications to the affected area, and adequate parenteral fluid, solution of glucose, saline solution, and vitamin replacement therapy. Parenterally administered sulfonamide compounds and blood transfusions may be of value.

In the subacute stage, efforts are directed toward eliminating the residual perifistulous inflammation,

decreasing the passage of intestinal contents through the fistula, and improving the patient's general condition.

Before instituting definitive surgical treatment for chronic persistent fecal fistulas, the following conditions should be met if possible. The etiological factors which are responsible for persistence of the fistula should be determined; the segment of intestine from which the false communications have their origin should be determined; it should be known whether the bowel distal to the lesion is patent; an adequate trial of conservative management should have been made; the general condition of the patient should be evaluated; all evidences of acute inflammation about the fistulous tract should have subsided.

Conservative surgical treatment, such as short-circuiting or sidetracking procedures, is used when the patient cannot meet the prerequisites for a more extensive, direct surgical approach.

In applying resection methods in the treatment of persistent, external fecal fistulas, the incision should, when possible, encircle and excise the fistulous tract; in most cases the results will be best if the peritoneum is opened and the affected segment of bowel is mobilized and inspected; all diseased tissue should be removed.

The types of persistent external fecal fistulas in which treatment is most difficult are (a) those in which the patient is a woman and the original pathological condition was pelvic inflammatory disease with pelvic peritonitis, (b) those in which the fistula arises in a region affected by severe diverticulitis with perforation, (c) those in which the fistula passes through bone, and (d) those in which the fistula is associated with enteroabdominal actinomycosis.

In the 65 cases of persistent external fecal fistulas of this series, in each of which treatment was surgical, there were 2 hospital deaths (3 per cent).

CHARLES BARON, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

McNamara, W. L., Baker, L. A., and Costich, K.:
Aneurysm of the Hepatic Artery. *Ann. Surg.*,
1946, 123: 427.

The authors report the case of a 44 year old man who was admitted to the hospital because of rheumatic heart disease, cardiac enlargement, and auricular fibrillation. While in the hospital he developed jaundice and a mass was palpable below the liver's edge. At operation the mass was found to be posterior to the gall bladder and ducts. Aspiration revealed blood and the diagnosis of aneurysm of the hepatic artery was made although the mass did not pulsate. No further surgery was attempted because of the patient's cardiac condition. The patient died 10 days after operation because of perforation of the aneurysm of the hepatic artery. There was no evidence of syphilis.

In reviewing the literature the authors found the suggestion that the artery be ligated because as the aneurysm develops, collateral circulation develops by way of the inferior phrenic artery. The mortality rate following ligation of the hepatic artery has been about 75 per cent in cases of aneurysm and about 60 per cent in conditions other than aneurysm.

EARL O. LATIMER, M.D.

Efskind, L.: Liver Changes in Surgical Conditions.
Acta chir. scand., 1946, 93: 81.

The author studied, by means of liver biopsies, the liver changes in surgical conditions. Biopsies were taken from the left lobe of the liver by means of a sharp instrument at the beginning and at the conclusion of operations. The specimens were examined for glycogen and fat content. The behavior of the mitochondria was scrutinized, while an attempt was made to study the circulatory condition from the appearance of the sinusoids. The author also observed the general cytological conditions in the liver cells themselves and the interlobular formations. The liver biopsies from a group of 120 patients were studied.

It was found that in patients with various serious disorders in the intestinal tract histological changes of a regressive nature were present in the liver cells. These changes were most pronounced in patients with protracted nutritional disturbances, hypoproteinemia and anemia, and in those with disorders of the liver and bile ducts. Topographically, these changes occurred at certain places of predilection in the lobuli of the liver and were considerably accentuated during severe operations. Also normal livers may show the same changes after severe operations, but in a minor degree. These changes occur in the following order:

- a. Abnormal mobilization of the liver glycogen
- b. Mitochondrial changes of a regressive nature
- c. Interstitial lymphocyte infiltration, sometimes with fibrosis

- d. Fat infiltration of the liver cells

The changes in the liver cells appear earliest and are most pronounced in the central parts of the lobuli. The fat infiltrated cells may often be well supplied with glycogen and frequently maintain their glycogen deposit for a long time, probably because of a kind of cellular blockade. The same may be seen in cases of chronic icterus and of considerable degenerative changes in the liver cells. Patients in whom the liver, in spite of adequate preliminary treatment, contains little glycogen and much fat show an abnormally great postoperative fall in serum proteins, with an inordinately long restitution time. The Kupffer cells show proliferative changes and in many cases a deposition of pigment or fat. The interstitial hepatitis seems to have arisen on a vascular, probably lymphogenic basis. Cholangitic infection has not been observed, even in cases of choledochal occlusion with infection.

EARL O. LATIMER, M.D.

Hudson, P. B., and Johnson, P. P.: Hemorrhage from the Gall Bladder. *N. England J. M.*, 1946, 234: 438.

The authors report 4 cases of hemorrhage into or from the gall bladder. Prior to this report 24 case reports appeared in the literature.

The first patient was 57 years old and had a severe anemia and melena of undetermined origin. X-ray examination of the gastrointestinal tract did not reveal any lesion, but the gall bladder was diagnosed as being diseased. The gall bladder was removed, and it was found to be distended and filled with stones and blood clots. The pathological diagnosis was malignant hemangioendothelial sarcoma.

In the 3 other cases blood was found in the gall bladders which also contained stones; in addition there was an acute or chronic cholecystitis.

EARL O. LATIMER, M.D.

Rienhoff, W. F., Jr., and Pickrell, K. L.: Pancreatitis: An Anatomic Study of the Pancreatic and Extrahepatic Biliary Systems. *Arch. Surg.*, 1945, 51: 205.

The authors examined the pancreas of 250 adults, both fresh and fixed specimens. The main and accessory pancreatic ducts were dissected out. In 73 instances (24%) they could find no junction of the pancreatic and bile ducts. In 92 specimens (37%) the common bile duct and the pancreatic duct were contiguous, and the dividing septum terminated from 1 to 2 mm. from the apex of their common orifice. In this group, however, a true ampulla was not considered present. In 81 instances (32%), a true ampulla was present, varying in length from 3 to 13 mm., while in 4 instances (2%), the main pancreatic duct was reduced to a fibrous cord. In 47 instances (18%), the length of the ampulla exceeded the

Fig. 1. A, The most constant arrangement of the pancreatic ducts. B, Specimen with three papillae. C, Dissected specimen of an adult pancreas showing an embryonic type of duct system in which the accessory duct carries most of the pancreatic secretion. D, Dissected specimen of an adult pancreas showing an unusual loop configuration of the main pancreatic duct.

Fig. 2. Variations of the entrance of the main pancreatic duct into the common duct.

average diameter of the duodenal orifice and a complete block at the papilla would convert the two ducts into a communicating system.

The average diameter of the duodenal papilla was 3 mm., with limits of 1.5 and 4.5 mm.

Concerning the accessory pancreatic duct, in only 89 of 100 specimens studied for this purpose could any intraglandular communication between the ducts be demonstrated. In 4 instances the embryonic duct system was present, i.e., the accessory duct carried the greater part of the secretion, while the main duct was reduced to a fibrous cord; 85 specimens had a normal duct arrangement. In only 62 of these (73%) was the duct found to be patent; in other words, there were 23 instances in which the accessory duct did not communicate with the duodenum, regardless of the duct arrangement; this made a total of 34 per cent in which fluid could not pass from the main pancreatic duct to the duodenum

by way of the accessory duct. The average diameter of the undistended duct at the duodenal perforation was 1.6 mm.

EARL O. LATIMER, M.D.

Reyes, H.: Acute Pancreatitis and Splanchnic Block (Pancreatitis aguda y bloqueo anestésico del esplácnico-semilunar). *Arch. Soc. cir. hosp.*, 1945, 15: 723.

Three cases of pancreatitis in which lumbar sympathetic block was exhibited are reported. Two cases were operated upon, one presenting gallstones and inflammatory changes about the sphincter of Oddi and the other requiring drainage of an abscess which was secondary to a hemorrhagic type of acute pancreatitis. The third case was considered mild and treated conservatively. A diagnostic and therapeutic approach is given in view of these experiences.

When acute pancreatitis is suspected, the necessary laboratory studies, including those of the

amylase values of the blood and urine, are made. A lumbar sympathetic block is done, which presumably alleviates pain and shock. This permits an air contrast x-ray study of the stomach, to visualize the changes which have occurred in the region of the pancreatic shelf. These steps being promptly carried out, information concerning the type of pancreatic involvement is obtained and the type of therapy is indicated. The block is believed to favorably affect the local disease process, promote drainage of bile by its effect on the sphincter of Oddi, and lead to general improvement by interrupting impulses originating at the site of the disease.

Roentgenographic illustrations of the pneumogastrographic findings are appended to the relatively detailed case report. **HIRSH T. LANGSTON, M.D.**

Curtis, G. M., and Moritz, D.: The Surgical Significance of the Accessory Spleen. *Ann. Surg.*, 1946, 123: 276

The end-result of splenectomy for certain diseases involving the formed elements within the blood, and particularly for congenital hemolytic icterus or primary thrombocytopenic purpura, is influenced by whether accessory spleens which may be present are found and removed. That the unremoved accessory spleen may eventually cause a recurrence of either congenital hemolytic icterus or primary thrombocytopenic purpura subsequent to splenectomy is established by observation of three types: first, recurrence associated with an accessory spleen found, but not removed, at the time of splenectomy, since its significance was not then recognized; second, recurrences associated with accessory spleens overlooked at the time of splenectomy, but subsequently found at autopsy, after the patient had died of recurrence; and third, the most convincing of all, relief from a recurrence by the surgical removal of accessory spleens at a second operation.

The authors' report is based on 174 consecutive splenectomies, and on 4 explorations for splenic disease. One hundred and thirty-one accessory spleens were found in 56 of these patients, an incidence of 31.4 per cent. The two diseases for which the accessory spleen should be removed to prevent recurrence, namely, congenital hemolytic icterus and primary thrombocytopenic purpura, were also the two most frequent indications for splenectomy, which was performed in 53 and 33 instances, respectively.

In general, there is a greater incidence of accessory spleens among young persons. In the authors' cases there was an incidence of 50 per cent among patients in the first decade, and of 39.1 per cent among those in the second decade, which is greater than the increased incidence of accessory spleens ordinarily found in the young with "normal" spleens. In patients with hemolytic icterus, accessory spleens occurred in 57.1 per cent of those in the first decade, and in 42.8 per cent of those in the second decade of life. In patients with primary thrombocytopenic purpura, accessory spleens were found in 44 per cent

of those in the first decade and in 33.3 per cent of those in the second decade. The number of accessory spleens per patient varied from 1 to 10, 26 patients presenting but 1 accessory spleen. The size of the accessory spleens herein described ranged from 2 mm. in diameter to 3 by 2 by 2 cm.

A condition referred to as "splenosis," in which splenules in great numbers are scattered throughout the peritoneum appears to be a different clinical entity than true accessory spleens. Usually they originate by transplantation of fragments of splenic tissue, scattered about the peritoneum by hemorrhage from a ruptured spleen. This mechanism becomes of clinical significance during splenectomy for primary splenic disease, since the spleen may be accidentally torn either during manipulation or dislocation of capsular adhesions. Autotransplantation may thus occur from the fragments, and in a patient with congenital hemolytic icterus it is reasonable to assume that such might result in a recurrence. The authors believe that 1 case of this type has been reported in the literature although it was not originally so identified (McLaughlin, C. W., Jr. *Surgery*, 1942, 12: 419-425). Moreover, since splenic substance may even transplant to subcutaneous tissue, the incision should be protected during splenectomy in the event that the spleen is traumatized.

To avoid overlooking accessory spleens, a routine search should be made after the major spleen has been removed, and hemostasis effected in the following approximate order: (1) the hilar region; (2) the splenic pedicle; (3) the retroperitoneal region surrounding the tail of the pancreas; (4) the great omentum, and especially along its attachment to the greater curvature of the stomach; (5) the splenocolic ligamentary attachments; (6) the mesentery of both large and small intestines; and (7), in the female, the left adnexa. Because in 3 of 4 proved recurrences the overlooked accessory spleens were later found in the retroperitoneal region, about the tail of the pancreas, this area should be searched with special care.

In this series of cases the accessory spleens were distributed as follows: hilar, 54.2 per cent; pedicle, 25.3 per cent; omentum, 12.2 per cent; retroperitoneum, 6.1 per cent; splenocolic ligament, 1.5 per cent; and bowel mesentery, 0.75 per cent. In 85.7 per cent of the patients, the accessory spleens were found in but a single location, and in only 8 instances were accessory spleens found in two different locations. In all instances of double location, the hilus constituted one location. Consideration of the embryonic development of the spleen provides an understanding of the occurrence of accessory spleens as well as their various locations. Even left scrotal and mediastinal splenic masses may occur.

In 2 cases there was a recurrence of the disease following splenectomy, which was attributed to accessory spleens. One patient had primary thrombocytopenic purpura that recurred 2 years after splenectomy; at autopsy, 2 accessory spleens were found in the retroperitoneal region near the tail of the pancreas. The other patient had congenital

hemolytic icterus that recurred about 4 years after splenectomy. At a second operation, 2 small accessory spleens were removed from the retroperitoneal tissue over the tail of the pancreas. Two years later the patient remained free from any evidence of recurrence of the disease.

Two cases from the literature are briefly summarized; in both cases accessory spleens were found and appeared to be the cause of recurrence.

Pedunculated accessory spleens may cause acute abdominal symptoms from infarction due to pedicle torsion, and this is shown in a summary of 2 such case reports obtained from the literature (Settle, E. *Am. J. Surg.*, 1940, 50: 22-26).

CHARLES A. WAITMAN, M. D.

MISCELLANEOUS

Gordon-Taylor, G.: The Last 'Hate.' *Brit. J. Surg.*, 1946, 33: 230.

This article is an account of abdominal injuries sustained from the V1 and V2 bombs and the shelling of Dover. These injuries, fortunately, were not numerous—only 120 patients being submitted to operation. Of the 79 patients submitted to operation with intraperitoneal visceral injury due to the V1 flying bombs, 60 recovered (76%). Of the 13 explored in whom hemoperitoneum was found without visceral injury, 1 succumbed. The V2 rocket bomb caused 16 cases of intraperitoneal injury with 9 recoveries (56.2%). Of 6 patients with intraperitoneal injuries received during the shelling of Dover, 1 died postoperatively. Cases of "crush syndrome," retroperitoneal hematoma, and non-penetrating abdominal wounds are not included in these figures.

Injuries due to the flying bomb were less serious than those due to high explosive bombs. Property damage was greater than the damage to people, and casualties were usually secondary to the blast effects on buildings. Many writers have commented on the infrequency of intra-abdominal injury as a result of V1 explosions. Of the 79 patients in this series, 14 had no external wound and were suffering from intra-abdominal damage produced by blast or the collapse of buildings. A high percentage of wounds were due to splintered glass, and in this series most of the abdominal viscera were on occasion damaged by glass—the intestines, liver, spleen, the left gastric artery, and the pregnant uterus.

Of the 92 patients in this series who were submitted to laparotomy, 50 were females. The author presents 2 cases in which the fetuses were injured in utero and died later. Eight patients were under 10 years of age and 8 over 65. The eldest, 86 and with numerous intestinal wounds, died on the operating table. The flying bomb seemed to have a predilection for children, and the author presents the histories of 2 cases of blast injuries, 1 patient aged 7 and the other 15. At operation both had a hemoperitoneum without visceral damage, and both patients recovered.

The author refers to Kidd's case of successful suture of the inferior vena cava, previously reported in the *British Journal of Surgery* (1945).

A case is presented of a woman who claimed that a flying bomb fell on her. A wound of her right buttock communicated with her abdomen, and she was in shock. At operation, hemoperitoneum, bruising of the sigmoid colon and mesosigmoid, and a 3 inch tear in the serous and muscular layers of the sigmoid were found. The operation was quickly terminated because of the patient's poor condition. At reoperation the next day more blood had collected in the abdominal cavity but the bowel was all viable and no more lesions were found. The patient ultimately recovered.

Three cases are presented of patients who were hospitalized at the time they received their abdominal injury from the V1 bombs. Two of these recovered.

The author has 3 cases in his series of abdominal injury due to antiaircraft fire during the V1 phase. He gives the case history of a 68 year old warden with an abdominothoracic wound with recovery. A piece of metal entered the epigastrium and passed through the diaphragm and pericardium to lodge in the right ventricle. This was removed and the wound in the heart sutured. The patient recovered and was able to resume his ordinary duties troubled only slightly with dyspnea.

Of the 16 abdominal visceral injuries due to the V2 bomb which were submitted to operation, about one-half were due to crushing with associated fractures of the pelvis and other bones. Several dramatic cases are presented. A 52 year old woman had her abdomen impaled by a rafter beam which entered the right lumbar region below the 12th rib and projected out of the abdominal wall in the left iliac fossa. The greater omentum was traversed but both the large and small bowel were only bruised and not lacerated. This patient recovered from this wound without the development of a herniation. A case of a railway man crushed between two railway trucks at the moment of a rocket incident is presented. He recovered after 8 feet of small intestine were resected and a laceration of the bowel was sutured. A 12 year old girl recovered after exteriorization of the colon because 5 or 6 inches of the mesosigmoid had been separated from the bowel by the blast of a V2 bomb. A case is presented in which severe damage to the liver and free portions were found in the abdominal cavity. The patient, a 15 year old boy, recovered. A woman recovered from a fragment wound in the right hypochondrium which shattered the eighth and ninth ribs and caused herniation of the liver, gall bladder, and colon through the wound.

Several cases of abdominal injury due to the shelling of Dover are presented. An American soldier recovered from multiple injuries caused by an exploding shell, a fragment of which penetrated his abdomen and passed through both walls of the stomach. Postoperatively, he developed intestinal obstruction and had to undergo a second laparotomy

INTERNATIONAL ABSTRACTS OF SURGERY

for relief from the adhesions. Subsequent recovery was uneventful. A remarkable plastic result was achieved by Rainsford Mowlem in a case of a woman with a severe perineal wound due to a shell fragment. He successfully reconstructed the vaginal and anal orifices.

A very remarkable recovery of a patient of the author is presented. A 39 year old woman was wounded in the upper left abdomen. The liver and everted stomach were visible through the anterior wound. Through the posterior exit wound, the colon protruded. The patient had numerous other puncture wounds of both legs. At operation, 3½ hours after wounding, several tears in the liver were sutured. The spleen which was pulsed was removed, a partial detachment of the diaphragm was repaired, and a 6 inch longitudinal tear in the stomach which led to the turning inside out of the vena was sutured. The patient ultimately made a good recovery.

ROBERT R. BIGELOW, M.D.

Newson, A., Watson, D., and Rose, T. F.: Early Results in a Short Series of Cases of Gunshot Wounds of the Abdomen. *Med. J. Australia*, 1946, 1: 180.

The authors present 27 cases of wounds of the abdomen which were treated in a forward unit in the Southwest Pacific area. The wounds were from 4 to 16 hours old when seen, and were caused by rifle bullets, machine gun bullets, mortar, high explosive, grenade or land mine fragments.

The treatment is briefly discussed, with emphasis on resuscitation by blood transfusions and blood plasma. The operative treatment of the 23 cases requiring laparotomy was not described. The post-operative treatment included gastroduodenal drainage, fluids, plasma, blood transfusions, and penicillin intramuscularly.

Nine patients had solid visceral injuries only. Of these, 6 had an uneventful convalescence. Two patients developed a wound infection and a biliary fistula, but ultimately recovered. One patient with a shattered liver died from irreversible shock.

Eighteen patients had wounds of the bowel. Of these, 5 recovered without complications; 4 had pulmonary emboli or intra-abdominal infection, but recovered; and 9 died (2 from irreversible shock, 1 from traumatic uremia, 1 from a hyperpyrexia, 1 from fecal peritonitis, 1 from an associated penetrating wound of the brain, and 1 following removal of the remnants of his only kidney—congenital absence).

Of the patients who recovered, 10 were back at their regular jobs in from 2 to 3 months, 1 was discharged from the Army as fit for sedentary work, and the other 4 were either in convalescent depots or about to be sent there, 3 months after being wounded.

THOMAS C. DOUGLASS, M.D.

Thornton, T. F., Jr., Storer, E. H., and Dragstedt, L. R.: Supradiaphragmatic Section of the Vagus Nerves. *J. Am. Med. Ass.*, 1946, 139: 764.

Following extensive studies of the effect of supradiaphragmatic section of the vagus nerves on gastric secretion and motility in patients with peptic ulcer, the authors conclude that:

1. The continuous night secretion of gastric juice in the empty stomach of patients with gastric and duodenal ulcers is usually much greater than in normal man.

2. This hypersecretion is chiefly neurogenic in character, and is much reduced by section of the vagus nerves to the stomach.

3. The empty stomach of ulcer patients often displays a hypertonicity and hypermotility, with exaggerated hunger contractions, and these are returned toward the normal state after bilateral vagotomy.

4. Complete section of the vagus nerves to the stomach in man abolishes the secretion of gastric juice produced by a sham meal or by insulin hypoglycemia, but has little or no effect on the response to histamine or caffeine. The absence of a secretory response to a sham meal or to insulin hypoglycemia is evidence that section of the vagus nerves to the stomach has been complete. CHARLES BROWN, M.D.

GYNECOLOGY

UTERUS

Fahlund, G. T. R., and Broders, A. C.: Postmenopausal Endometrium and Its Relation to Adenocarcinoma of the Corpus Uteri. *Am. J. Obst.*, 1946, 51: 22.

The question of whether a given malignant neoplasm passes through a premalignant phase is often raised, and hence should be considered as fundamental. Since the problem obviously is closely allied with early diagnosis and treatment, the question is not purely academic, but practical as well. Thus, if a premalignant phase could be definitely established, physicians could strive to diagnose the condition during this period and eradicate it, with consequent prevention of the malignant neoplasm. The foregoing fundamental question prompted a study of the postmenopausal endometrium and its relation to adenocarcinoma of the corpus uteri.

The material studied consisted of postmenopausal uteri in 236 cases. In 86 of the cases the uterus had been removed because of adenocarcinoma, and in 100 cases it had been removed for other reasons. In 50 cases routine necropsy had been performed.

In the group of 86 women who had adenocarcinoma of the corpus uteri, all but 1 had had vaginal bleeding or spotting as a presenting complaint.

In the 86 cases of adenocarcinomatous uteri, there was no appreciable variation in the percentage of cases with proliferative endometrium, whether early or late, or in the percentage of cases with atrophic endometrium, according to the grade of malignancy.

There was no appreciable difference in the percentage of cases of any given type of endometrium in adenocarcinomatous uteri as compared with nonadenocarcinomatous uteri, except with regard to atrophic endometrium. Thus, 41.8 per cent of cases of uteri with malignancy showed atrophic endometrium, and only 16 per cent of cases of uteri without malignancy showed atrophic endometrium. This suggests that adenocarcinoma of the uterine corpus is more likely to occur in cases in which there is atrophy of the endometrium than in cases in which there is no atrophy.

Two of the 86 cases of adenocarcinomatous uteri, and 3 of the 150 cases of nonadenocarcinomatous uteri presented some features similar to those found in early differentiative endometrium, but since they were not entirely the same the endometrium was classified as late proliferative.

The percentage of cases with cystic change (grades 3 and 4) and with accumulation of secretion (grades 3 and 4) was roughly the same in the two groups of cases. Approximately 42 per cent of adenocarcinomatous uteri showed no cystic changes, whereas 20 per cent of nonadenocarcinomatous uteri showed no cystic changes. This lends evidence which is contrary to the view that the "swiss-cheese endome-

trium" of Novak has any features predisposing to the development of carcinoma.

There was no consistent difference or variation of cystic change, accumulation of secretion in the glands, density of the stroma in and beneath the endometrial epithelium, involvement of the sub-basal glands, or sclerosis of the arteries and arterioles, according to the grade of adenocarcinoma. In 28 of the 86 cases, no sub-basal glands were found. Thus, sub-basal glands seem to have no causal relationship to adenocarcinoma of the uterus.

There was virtually no difference in average thickness of endometrium in adenocarcinomatous uteri, compared with nonadenocarcinomatous uteri.

The incidence of endometrial polypi in uteri without adenocarcinoma was, roughly, eight times greater than their incidence in uteri containing adenocarcinoma. However, previous curettage in all cases of malignancy might be partially responsible for the variation.

In general, it may be concluded from this comparison of adenocarcinomatous and nonadenocarcinomatous uteri removed from women who had passed the menopause, that the uninvolved portion of endometrium in the former group was in no demonstrable way different from that of the endometrium in the latter group except that atrophic endometrium was found more often in adenocarcinomatous uteri than in nonadenocarcinomatous uteri, while endometrial polypi were found more often in nonadenocarcinomatous uteri.

Stowe, L. M.: A Histological Study of the Effect of Irradiation on Adenocarcinoma of the Endometrium. *Am. J. Obst. Gyn.*, 1946, 51: 57.

The literature dealing with the detection of residual tumor and its frequency in adenocarcinoma of the endometrium treated with radium, radon, and deep x-ray therapy was reviewed by the author. The reports show persistence of apparently viable tumor in from 12.5 to 89 per cent of the cases. There was wide variation in the amount of therapy given, in the type of radium or radon applicators used, in the intervals between irradiation therapy and operation, and in the thoroughness of the search for residual tumor in the operative specimens.

The incidence of residual tumor in the uteri of the 53 patients studied was 50.9 per cent. All of these patients were given intrauterine applications of radium; 23 had deep x-ray therapy as well. In a small series in whom x-rays were employed in adequate dosage together with radium irradiation, the incidence of residual tumor fell to 40 per cent, while in a larger series in which radium alone was used, the incidence was 56.5 per cent.

An applicator designed to overcome the effect of variations in size and shape of the uterine cavity is described. It was used in 46 of the 53 cases.

In the majority of instances in which residual carcinoma was found, it was seen in the musculature of the uterus. The significance of this is discussed.

In view of the fact that tumor persisted after irradiation in a high percentage of cases, and especially in view of its frequency in the myometrium, it is concluded that surgical attack must be considered the essential feature of curative therapy in the treatment of adenocarcinoma of the corpus uteri. It is still possible that preliminary irradiation may be useful as additional therapy or for palliation.

EDWARD L. CORNELL, M.D.

Corscaden, J. A., Fertlg, J. W., and Gusberg, S. B.: Carcinoma Subsequent to the Radiotherapeutic Menopause. *Am. J. Obst. Gyn.*, 1946, 51: 1.

Among 938 patients treated for benign uterine bleeding by induction of the radiotherapeutic menopause and followed up for an average of 6.7 years each, there subsequently occurred 15 carcinomas of the uterus. Based on the modified mortality statistics, the same number of women in the general population during the same length of time should contract 4.4 carcinomas of the uterus. The observed number of cases is therefore 3.4 times as large as the number expected.

Two and eight-tenths per cent of the women in the general population between the ages of 30 and 55 years contract cancer of the uterus before reaching the age of 80. Applying the ratio of 3.4, we find that 9.6 per cent of the women suffering from uterine bleeding prior to the menopause would contract it.

Of 15 cases, 9 were of the corpus and 6 of the cervix. This abnormal preponderance of carcinoma of the corpus is in agreement with that present in other reported cases in which the ratio is 2 of the corpus to 1 of the cervix. This ratio of corpus to cervix is 6 times that obtaining in the clinic.

It is inferred that the endometria of uteri which bleed abnormally prior to the menopause are predisposed to the subsequent development of carcinoma of the corpus.

Prophylaxis against carcinoma of the uterus should be an important factor in a plan of treatment for uterine bleeding prior to the menopause.

EDWARD L. CORNELL, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Glanfrant, T.: Neoplasms in Apparently Normal Ovaries. *Am. J. Obst. Gyn.*, 1946, 51: 246.

The author has examined the ovaries at all operations in which this was possible in the service of the Graduate Hospital, Philadelphia, Pennsylvania, and in the past 3 years the following tumors were found in approximately 1,500 ovaries that appeared normal: 3 dermoids, 1 Brenner tumor, 1 fibroma, 1 papillary cyst adenocarcinoma, and 1 granulosa cell tumor. Two of these tumors were discovered in the routine pathological examination of the ovaries removed at operation; 5 of them were found by examination of the ovaries during the operation.

These small neoplasms ranged in size from a few millimeters to 1.5 cm.; none of the ovaries that harbored them were of more than normal size.

These tumors comprise a group of extreme interest in themselves, but a more important consideration lies in the practical aspect of the problem presented by their presence in apparently normal ovaries. Although they were mere infant growths when discovered, they would have enlarged eventually, but their early discovery and removal averted serious consequences.

The 7 cases are briefly discussed.

MISCELLANEOUS

Da Silva Pereira, J. M.: Prolapse of the Urethra in the Female; Considerations Based on 3 Personal Observations (Prolapso de uretra feminina, considerações em torno de 3 casos). *Obst. gyn. lat. am.*, 1945, 3: 848.

The first of these 3 patients was a woman, 67 years of age, with senile involution of the sexual organs. First she had polyuria and later developed such dysuria as to make it necessary for her to urinate with great difficulty in a hot bath. Ten days before examination she noted a tumor of the vulva and began to pass blood with the urine. Examination disclosed an almond sized, cyanotic, bleeding mass at the external meatus of the urethra which had become strangulated at the base. Operation consisted in splitting the collarlike excrescence on both sides down to the base, cutting away the upper flap, and suturing the remaining mucosa to the edge of the meatus with interrupted, fine, chromic catgut. The lower flap was also cut away and the incision extended back along the upper wall of the vagina, deep sutures being then applied, much as in the Hegar perineal repair, so as to produce a narrowing of the urethral lumen. An indwelling catheter was kept in position for 5 days and the completed the treatment. A photograph, a month later, shows the condition still perfectly corrected.

The second patient was a child of 9 years, whose condition was discovered in the bath. The operation was the same as in the first instance, except that the lower flap was sutured in the same manner as the upper without an attempt at urethral repair. A half year later re-examination disclosed a perfect result.

The third case, that of a child of 10 years of age was operated upon in the same manner as the second except that the indwelling catheter was omitted; nevertheless, the result was as good as in the other case.

The author emphasizes the predominance of this lesion in the extremes of life and the good results to be expected by almost any of the methods of treatment previously proposed, provided that the condition be recognized early, before strangulation and infection render treatment difficult and dangerous.

The classification adopted by the author differs somewhat from those of previous writers on the subject.

ject; first degree prolapse is a prolapse of only a part of the circumference of the mucosa at the external meatus; second degree prolapse is a protrusion of the entire circumference of the anterior section of the urethral mucosa, and third degree prolapse is the protrusion of both the anterior and posterior segments of the mucosal cylinder lining the urethra.

JOHN W. BRENNAN, M.D.

Pérez, M. L., Arenas, N., and Bolla, I.: Immediate and Terminal Results of the Surgical Treatment of Genital Prolapse (Resultados inmediatos y alejados del tratamiento quirúrgico del prolapso genital). *An. Inst. maternidad*, B. Air., 1944, 6: 9.

The authors report on 200 operations for genital prolapse performed in the gynecological section of the Institute for Maternity and Social Assistance in Buenos Aires from 1935 to 1943 inclusive. Seventy cases could be followed up to the present time and these are arranged in a table which makes up the greater part of the article. In all, the results were satisfactory, not a single instance of recurrence being observed.

Sixty-two of the 70 patients were under 60 years of age and in all of these the technique of Halban had been applied; the remaining 7 were more than 60 years old and in these the Le Fort technique had been done. In 7 patients in whom there was some loss of control of the urine a torsion operation on the urethra (2 instances), or the technique of Marion for narrowing the urethral lumen (5 cases) was added. In 1 senile patient the technique used was that of Kahr.

The technique of Halban was followed by preference under low spinal anesthesia with novocain, but occasionally local or general anesthesia was used. In cases of retroversion, the uterus was fixed to the highest part of the vesical peritoneum. Amputation of the cervix was done in 24 of the 70 patients, but only when the uterine cavity measured more than 8 cm. on hysteroecomy. Colpoperineorrhaphy with myorrhaphy of the puborectal muscle slips of the levator ani was performed in most cases; however, this was done only in the presence of a low rectocele with a bad perineal tear.

There was 1 case of death from pulmonary embolism. Three cases developed a postoperative vaginoperineal fistula and 1 case a rectoperineal fistula.

Several of the 200 patients are reported to have passed through a perfectly normal pregnancy, and in 1 of the 70 patients who were followed up a normal pregnancy and delivery was followed by a second pregnancy since the operation, without recurrence of the original condition. JOHN W. BRENNAN, M.D.

De Jaegher, M.: The Adrenogenital Syndrome of the Girl with Pseudohermaphroditism (Sur le syndrome adrénogénital de la fillette à forme de pseudo-hermaphroditisme). *Rev. belge sc. med.*, 1942, 14: 346.

The adrenal cortex exerts a decisive influence upon the harmonious development of the sexual mor-

phology and physiology. This interrelation is also indicated by the names proposed for certain pathological states such as the "adrenogenital syndrome" and similar ones.

If the adrenocortical dysplasia develops in the first months of life, a pseudohermaphroditism results because of the appearance of secondary sexual characteristics from both sexes.

The appearance of an adrenogenital syndrome in the newborn, probably pre-existing during fetal life, affects the development in a much more profound and less reversible manner than the development of this syndrome during puberty or the menopause. Twenty-six cases of infantile adrenogenital syndrome have been reported, 21 of which occurred in girls.

The author reports a case in which the father of the girl had a history of active pulmonary tuberculosis. The girl developed normally up to the age of 15 months; at that time she showed a minimal amount of vaginal bleeding, which her mother considered a precocious menstruation. At the age of 18 months, hair appeared on the large labia, and the latter became hypertrophic at the age of 2 years. The voice turned harsh and a tendency toward masturbation was noted.

At the age of 3 years and 2 months the child was first examined and was found slightly overdeveloped in size (corresponding to 4 years), but with ossifications of the wrist bones, corresponding to age 12, no anomalies of the skull or sella turcica were found. The tuberculin test was positive. The girl was of dark complexion with slightly pigmented spots, dark hair, and bushy eyebrows. A light hair growth was seen on the upper lips, thighs, and calves. The chest was well developed, the pelvis appeared to be masculine, the legs were short with incomplete syndactylism of the second and third toes. The suprapubic region and the large labia were hairy. The large and small labia and the clitoris were hypertrophic with the external urethral opening on the undersurface of the clitoris. The vagina appeared to be of normal size. There was some mental retardation. A roentgenogram of the adrenal regions revealed a calcified tumor of the left adrenal gland. Laboratory findings including urine tests for male and female sex hormones revealed no abnormality.

A clinical diagnosis of calcified left adrenal tumor was made; 2 days after surgical extirpation of the tumor, the child died in shock. The autopsy revealed a recent caseous tuberculosis of the mesenteric ileocecal glands without a visible intestinal lesion and without a pulmonary lesion. The liver showed steatosis. The histological examination of the central nervous system and of the diencephalon was negative. The liver and spleen showed traces of a recent toxic infectious process. One kidney was larger with a normal arterial supply, the other, and smaller, kidney showed a discrete chronic pyelonephritis.

The thymus showed large Hassall bodies, and the thyroid gland showed colloid accumulation. The hypophysis showed a predominance of acidophil

INTERNATIONAL ABSTRACTS OF SURGERY

cells. The ovaries appeared within normal limits with numerous follicles within the cortical zone and some graafian follicles in the central zone. There was no evidence of any stimulation of the ovaries by the adrenocortical tumor.

The left adrenal gland showed some toxic lesions, and the surgically removed right adrenocortical tumor revealed a microscopic picture which has been described by Goormaghtigh as typical for an adrenocortical tumor with masculinizing effects: (1) the presence of gross granulations arranged within the least atypical cells in halfmoons, which were stained by scarlet red, iron hematoxyline, and, at times, also by acid fuchsin; and (2) the gradual disappearance of the granulations into a marginal lacunar system. Broster has classified the effects of tumors of the adrenal cortex according to the type of tumor, and the age and sex of the patients, as follows:

- Androgenic tumors:
1. In the female child: masculine genital organs and pubertas praecox.
 2. In the female at puberty: masculinization of the genital organs and suppression of ovarian function.
 3. In the male child: pubertas praecox without spermatogenesis.
 4. In the male at puberty, no effects being noticeable.

Estrogenic tumors:

1. In the male child: found to be an extremely rare occurrence.

2. In the male at puberty: feminization, gynecomastia, impotence, and testicular atrophy.
3. In the female child: pubertas praecox without maturation of the ovaries, but with menstruation in certain cases.
4. In the female at puberty: no discernible effects.

ARTHUR J. LESSER, M.D.

Jones, H. O., and Doyle, L. W.: Studies of Surgical Morbidity. Effect of Prostigmine on the Urinary Tract in Gynecologic Surgery. *Am. J. Obst.*, 1946, 51: 184.

A study of the effect of prostigmine on the urinary tract following gynecologic surgery is presented. Eighty-five patients received the drug and 85 were used as controls. The incidence of postoperative urinary distress was the same in the treated as in the untreated group. The postoperative urinary findings were the same for both groups. The incidence of postoperative spontaneous voiding was the same in both groups.

"Gas pains" were somewhat lessened in the patients who received prostigmine, but in patients in whom obstruction existed, the discomfort was increased by prostigmine. The amount of "residual urine" was found to be the same in the patients who voided spontaneously as in those who had to be catheterized for urinary distress or distention. As used in the authors' study, prostigmine was ineffective in preventing postoperative urinary infections.

EDWARD L. CORNELL, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Trillat, P., and Notter, A.: Synostosis of the Pubic Symphysis. An Anatomic and Clinical Study (*La synostose de la symphyse pubienne. Considérations anatomiques et cliniques*). *Rev. fr. gyn. obst.*, 1945, 40: 321.

In studying a collection of 188 pelves at the Museum of the Obstetrical Clinic of Lyons, the authors observed a most peculiar anomaly in 1 pelvis, namely, a complete synostosis of the pubic bones. The specimen had been taken from a woman of 47 years and consisted of a symmetrical pelvis; the anteroexternal surface of the pubes and ischiopubic rami were very irregular and the internal margin bristled with exuberant exostoses. A veritable bony bridge connected the upper portion of the pubic bones. The superior synostosis was complete, which was confirmed roentgenologically, but a suture could be observed in the lower portion. Below the articulation, the ossified ends of the arch were plainly visible. The deformities along the margin of the hip bone and anterior surface of the pelvis resembled the lesions of rickets, but the more marked deformities in the inferior ischiopubic region suggested rather the inflammatory sequelae of osteomyelitis.

A search was made of the literature for cases of symphysiotomy in which such an anomaly might have prevented division of the symphysis. Some mention was found in the older literature of such instances, but emphasis was always placed on their extreme rarity. No mention of the condition was found in later literature. The incidence, according to clinical statistics, would be 13 in 670 patients. The authors examined specimens in other museums without success.

Just as the degree of ossification encountered in other articulations may vary, so the symphysis may display various degrees of ossification up to complete synostosis. Other possible etiological factors suggested include surgical injury, coxalgia, and acute osteomyelitic arthritis.

In a normal pelvis like the one described such a synostosis might cause no symptoms, and even labor might not be seriously affected. But in cases of constricted pelvis, such an anomaly would increase the dystocia. Synostosis constitutes a contraindication to symphysiotomy.

EDITH SCHANCHE MOORE.

NEWBORN

Baldi, E. M.: Hemorrhage of the Suprarenal Glands in the Newborn (*Las hemorragias de las cápsulas suprarrenales en el recién nacido*). *An. Inst. maternidad*, B. Air., 1944, 6: 159.

In 32 years of work at this institution, the author observed 10 infants with hemorrhage of the supra-

renal glands. Four of the infants had been borne by primiparas (1 of these had had a previous abortion), and 6 had been borne by multiparas. At periods from a few hours to 11 days following delivery (spontaneous in 7; by forceps in 2; by Kristellar expression in 1) the infants developed symptoms of the "pseudopneumonia of the newborn" of Goldzieher and Gordon (*Endocrinology*, 1932, 16: 165), of icterus and progressive anemia, of cerebral hemorrhage, or of just plain collapse (with or without fever) and died in a few hours or in a few days. The autopsies disclosed little else than the hemorrhagic accident into the right, or into both (in 3 of the 10 cases) of the suprarenal glands.

These 10 not unusual reports of this condition are offered rather less with the thought of adding what is startlingly new to medical experience than to remind us of how little attention has been allotted to the problem of suprarenal hemorrhage, and of how much interesting work has been done, particularly in North America recently. Particular stress is laid on the report of Corcoran and Strauss (*J. Am. M. Ass.*, 1924, 82: 626), in which they stated that recognition of the condition at operation permitted ligation of bleeding artery and recovery of the child, and that the establishment of the clinical syndrome "pseudopneumonia in the newborn," will enable earlier recognition and proper treatment of the condition in many cases.

The author tends to blame this grave accident of the newborn child to a great extent on the innermost layers of the cortical layer of the suprarenal capsule, the so-called "fetal cortex," androgenic zone, or zone X, and particularly on the confused degenerative processes which occur at about the time of the child's birth.

The usual therapeutic procedures for individual manifestations are recommended, such as blood transfusions for anemia, 10 per cent glucose solution for hypoglycemia, and vitamin K for hypoprothrombinemia—low values of the coagulative essential are very apt to be encountered at birth. Although admitting lack of practical experience in the matter, the author believes that, despite some unfavorable reports, the newer and more efficacious preparations of the cortex of the suprarenal gland should be given an adequate trial.

JOHN W. BRENNAN, M.D.

Mayes, H. W.: Cord Transfusions in Newborn Infants. *J. Pediat.*, S. Louis, 1946, 28: 69.

Following a long labor, difficult forceps delivery, or breech extraction, infants are frequently in severe shock. Not infrequently they are suffering from hemorrhage, and shock may not always be apparent at birth but develops shortly after. In premature babies the blood has a low content of vitamin K and prothrombin, and premature infants are much more subject to hemorrhage and will not withstand as

much trauma as full term infants. It would seem that if newborn full term infants following a difficult labor, and all premature infants were given some adult blood immediately following birth, such a transfusion might overcome shock, supply the needed vitamin K and prothrombin, and furnish nourishment and fully developed red corpuscles to be utilized in carrying on the circulatory functions.

Another hazard to the newborn infant is erythroblastosis. It would seem that the Rh factor alone does not determine or is not alone present in the development of the disease. Even more prognostic of its occurrence, particularly when found in infants of Rh-negative mothers, is a high count of normoblasts in the cord blood immediately or soon after birth. Transfusions would seem of value in the actual or prophylactic treatment of erythroblastosis.

Mother's blood is preferred for cord transfusion because at the time of delivery it contains more prothrombin and vitamin K than the average individual's, the vitamin K having been reinforced by administration during labor. If mother's blood is used only once, as is usually the case, it is not necessary to match the blood before giving the cord transfusion. Even if it is incompatible and although there may be some reaction, this one transfusion will assist the baby, since the blood will remain in the circulation long enough to exert its beneficial effect. The reason for this is the absence of agglutinins in the baby's blood at birth other than those derived from the mother.

The blood should be withdrawn before the birth under sterile precautions and placed on the delivery table. A 50 c.c. syringe containing sufficient citrate to insure against clotting in the syringe is used; 5 c.c. of a 2 per cent solution of sodium citrate is enough for 35 c.c. of blood. If 50 c.c. of blood are to be used, then 7 or 8 c.c. of the citrate are advisable. When the citrate is first drawn into the syringe, the entire length of the barrel should be moistened with it by withdrawing the plunger of the syringe and allowing the solution to come in contact with the entire inside of the barrel.

The amount of blood given depends upon the size of the baby and the reason for its use. The correct amount for a baby is about 10 c.c. per pound of body weight.

It is preferable to inject the blood before separating the baby from the mother. The baby is placed on the mother's abdomen or is held with the head down by an assistant. The cord is clamped and the blood injected into the umbilical vein. The cord should be steadied with the left hand, the barrel of the syringe grasped with the right, and the blood injected by making pressure on the plunger with the chest.

Great care should be taken after entering the cord vein. Should the point of the needle perforate the thin walled vein the blood will be injected into the substance of the cord, and a diffuse localized area of hemorrhage will appear. If this happens, the transfusion may be attempted again at a point nearer the

baby's body, provided the first attempt was made far enough away from the navel. It is important to select the first site at a maximum distance, usually about 12 inches, to allow for subsequent trials. A large, short bevelled, Fordyce needle obviates the danger of vein injury.

At times it is advisable to separate the baby from the mother before undertaking the transfusion. The cord is likely to collapse when cut and the veins are hard to identify. If the cord is milked toward the clamp, enough blood can be collected to identify the vein.

The giving of blood seems to have no ill effect on the baby. Frequently the respirations are stimulated, and the baby, previously pale in color, becomes pink.

The first cord transfusion at the Methodist Hospital, Brooklyn, New York, was given in 1940 to a premature infant. The first report on cord transfusions was published in 1944 by the author.

A total of 281 cord transfusions were done from 1940 through March, 1945. One hundred and thirty nine premature infants (37 weeks or under) received cord transfusions of their mother's blood, with 20 deaths; the majority of deaths occurred in infants of less than 7 months' gestation.

Forty-one babies were transfused following long labors or difficult deliveries with no deaths.

The babies of 110 Rh negative mothers received cord transfusions of their mother's blood. There were 2 deaths, both of premature infants.

A study was made of 601 cord smears; 288 contained no normoblasts, while 314 contained more than 15. Among these 314 infants there were 5 deaths and 1 stillbirth. Five of the 6 mothers were Rh positive. 1 was Rh negative. Of the 11 infants of Rh negative mothers in the group of 34, 9 received a cord transfusion, with 1 death, that of a premature infant.

A case is reported in which 90 c.c. of blood from the Rh negative mother of high titer (r:80) were given to her baby for marked jaundice with definite improvement in the baby's condition.

The author recommends cord transfusions to babies born of Rh negative mothers when the mothers have had a previous pregnancy. Use of mother's blood rather than donor's is contrary to the general rule, but so far the mother's blood seems to agree with the babies. Cord transfusions may be useful in anticipation of the development of erythroblastosis in infants of Rh negative mothers, or in its treatment when present at birth.

An addendum to the article states that there have been 117 additional cord transfusions between April 1 and December 1, 1945. Fifty-three of the transfusions were given to babies of Rh mothers, with mother's blood, making a total of 85 such transfusions this year with the loss of no viable babies from these mothers.

The total number of cord transfusions of mother's blood given to babies is 398. Two hundred and three of the babies were premature and 163 were babies of Rh mothers.

Wislocki, G. B., and Dempsey, E. W.: Histochemical Age Changes in Normal and Pathological Placental Villi (Hydatidiform Mole, Eclampsia). *Endocrinology*, 1946, 38: 90.

Observations on the occurrence and significance of lipoids, glycogen, iron, alkaline phosphatase, and basophilia in the human placenta have been made previously by the authors. They now add further important cytological and histochemical data regarding not only normal but also certain pathological placentas.

The material used in this study consisted of 20 normal placentas ranging in age from 6 weeks up to term. In addition to these, 2 hydatidiform moles and the placentas from 2 cases diagnosed, respectively, as of severe pre-eclampsia and eclampsia were studied. The material was carefully analyzed, chemically and histologically, according to well recognized and accepted techniques. The results were correlated with previous observations.

The occurrence of acid phosphatase in the placenta is reported here for the first time. It accumulates in the trophoblastic syncytium of the human placenta toward the very end of gestation. It occurs principally in the nuclei of the syncytium and to a lesser extent in the perinuclear cytoplasm. Alkaline phosphatase begins to appear in the syncytium in the first months of pregnancy and increases steadily until term. Thus these two enzymes characterize the ageing placenta; they occur in inverse proportion to cytoplasmic basophilic substance (ribonucleoprotein), which diminishes steadily as the placenta ages.

Iron and calcium are demonstrable in considerable quantities in the first half of gestation in the stroma

of the chorionic villi, where they are mainly deposited just beneath the trophoblastic epithelium. In the same localities and during the same period traces of acid and alkaline phosphatase are also encountered.

In the hydatidiform moles no acid phosphatase and relatively little alkaline phosphatase were found. There was definite histochemical confirmation of the known fact that the syncytium produces steroid hormones. No calcium and only diffuse traces of iron were demonstrable in the villi of the moles, but glycogen was present in both the cytotrophoblast and syncytium in amounts greatly increased over normal. The increases or decreases of these various substances in contrast to the amount of these substances in normal villi are referable to the absence of the fetal circulation and a diminished maternal circulation.

The 2 placentas from the cases of severe pre-eclampsia and of eclampsia were unusual. Both cases were atypical in so far as in each the condition was present at $4\frac{1}{2}$ months of gestation. The chorionic villi were prematurely aged as judged by their cytological and histochemical appearance. Many of the villi showed premature ageing of the syncytium, while a few of the very smallest terminal villi showed complete necrosis of both the stroma and syncytium. Ribonucleoproteins (cytoplasmic basophilia) were prematurely reduced, whereas alkaline and acid phosphatases were appreciably increased. There were also noticeable changes in the amount and distribution of both calcium and glycogen. The decrease in cytoplasmic basophilia associated with a premature increase in phosphatase suggests a possible disturbance of nucleoprotein metabolism in this disease.

L. JAMES TALBOT, M.D.

much trauma as full term infants. It would seem that if newborn full term infants following a difficult labor, and all premature infants were given some adult blood immediately following birth, such a transfusion might overcome shock, supply the needed vitamin K and prothrombin, and furnish nourishment and fully developed red corpuscles to be utilized in carrying on the circulatory functions.

Another hazard to the newborn infant is erythroblastosis. It would seem that the Rh factor alone does not determine or is not alone present in the development of the disease. Even more prognostic of its occurrence, particularly when found in infants of Rh-negative mothers, is a high count of normoblasts in the cord blood immediately or soon after birth. Transfusions would seem of value in the actual or prophylactic treatment of erythroblastosis.

Mother's blood is preferred for cord transfusion because at the time of delivery it contains more prothrombin and vitamin K than the average individual's, the vitamin K having been reinforced by administration during labor. If mother's blood is used only once, as is usually the case, it is not necessary to match the blood before giving the cord transfusion. Even if it is incompatible and although there may be some reaction, this one transfusion will assist the baby, since the blood will remain in the circulation long enough to exert its beneficial effect. The reason for this is the absence of agglutinins in the baby's blood at birth other than those derived from the mother.

The blood should be withdrawn before the birth under sterile precautions and placed on the delivery table. A 50 c.c. syringe containing sufficient citrate to insure against clotting in the syringe is used; 5 c.c. of a 2 per cent solution of sodium citrate is enough for 35 c.c. of blood. If 50 c.c. of blood are to be used, then 7 or 8 c.c. of the citrate are advisable. When the citrate is first drawn into the syringe, the entire length of the barrel should be moistened with it by withdrawing the plunger of the syringe and allowing the solution to come in contact with the entire inside of the barrel.

The amount of blood given depends upon the size of the baby and the reason for its use. The correct amount for a baby is about 10 c.c. per pound of body weight.

It is preferable to inject the blood before separating the baby from the mother. The baby is placed on the mother's abdomen or is held with the head down by an assistant. The cord is clamped and the blood injected into the umbilical vein. The cord should be steadied with the left hand, the barrel of the syringe grasped with the right, and the blood injected by making pressure on the plunger with the chest.

Great care should be taken after entering the cord vein. Should the point of the needle perforate the thin walled vein the blood will be injected into the substance of the cord, and a diffuse localized area of hemorrhage will appear. If this happens, the transfusion may be attempted again at a point nearer the

baby's body, provided the first attempt was made far enough away from the navel. It is important to select the first site at a maximum distance, usually about 12 inches, to allow for subsequent trials. A large, short bevelled, Fordyce needle obviates the danger of vein injury.

At times it is advisable to separate the baby from the mother before undertaking the transfusion. The cord is likely to collapse when cut and the veins are hard to identify. If the cord is milked toward the clamp, enough blood can be collected to identify the vein.

The giving of blood seems to have no ill effect on the baby. Frequently the respirations are stimulated, and the baby, previously pale in color, becomes pink.

The first cord transfusion at the Methodist Hospital, Brooklyn, New York, was given in 1910 to a premature infant. The first report on cord transfusions was published in 1944 by the author.

A total of 281 cord transfusions were done from 1940 through March, 1945. One hundred and thirty-nine premature infants (37 weeks or under) received cord transfusions of their mother's blood, with 20 deaths; the majority of deaths occurred in infants of less than 7 months' gestation.

Forty-one babies were transfused following long labors or difficult deliveries with no deaths.

The babies of 110 Rh negative mothers received cord transfusions of their mother's blood. There were 2 deaths, both of premature infants.

A study was made of 601 cord smears; 288 contained no normoblasts, while 314 contained more than 15. Among these 314 infants there were 5 deaths and 1 stillbirth. Five of the 6 mothers were Rh positive; 1 was Rh negative. Of the 11 infants of Rh negative mothers in the group of 314, 9 received a cord transfusion, with 1 death, that of a premature infant.

A case is reported in which 90 c.c. of blood from the Rh negative mother of high titer (r.80) were given to her baby for marked jaundice with definite improvement in the baby's condition.

The author recommends cord transfusions to babies born of Rh negative mothers when the mothers have had a previous pregnancy. GENITOURINARY SURGERY

ADRENAL, KIDNEY, AND URETER

Reiselman, S. D.: Early Amyloid Nephrosis following Compound Bone Injuries. *Vrachebnoe Delo*, 1945, p. 71.

As a rule, amyloid nephrosis is closely related to chronic diseases causing cachexia, especially pulmonary, osseous, or articular tuberculosis, and prolonged suppurative processes such as empyema, bronchiectasis, pulmonary abscess, and osteomyelitis. However, amyloid nephrosis may develop following processes of short duration. This observation is not only of diagnostic but also of great prognostic value because, in spite of the fact that the primary process may subside, amyloidosis may be responsible for a fatal outcome. The condition can be easily mistaken for a decompensated heart or chronic nephritis and incorrect treatment instituted. On the other hand, early recognition of the pathological process and an attempt to eliminate the primary pathogenic source of the disease may be followed by complete recovery.

The author stresses the fact that albuminuria accompanying amyloid nephrosis is not pronounced, but it is subject to considerable fluctuations. The urinary sediment is poor in formed elements when compared with the same degree of albuminuria in the other renal conditions. Edemas are not very pronounced and are more marked in the lower than in the upper extremities. Ascites is infrequent and hydrothorax rare.

When amyloid nephrosis is accompanied by amyloidosis of the intestines, diarrhea appears and the condition may then simulate enterocolitis, avitaminosis, or dysentery.

The author maintains that amyloid nephrosis is much more frequent following compound fracture than is generally assumed. He describes 28 cases in which the complication developed from 2 weeks to 3 months after a compound fracture with osteomyelitis. It would be difficult to believe that all 28 patients had had the amyloid nephrosis before the injury and that none of them had clinical symptoms before the trauma.

JOSEPH K. NARAT, M.D.
Fort, A.: Tumors of the Renal Pelvis (Tumores de la pelvis renal). *Rev. med. Rosario*, 1945, 35: 1213.

Tumors of the pelvis of the kidney are being reported much more frequently of late years, perhaps because of the better methods of diagnosis for this condition, developed by urologists. However, these tumors are still rather rare, even in comparison with the tumors of the body of the kidney itself. The author's material comprises only 4 cases in comparison with 14 cases of tumor of the kidney parenchyma. The author classifies tumors of the renal pelvis in general by more or less combining the classifications of Albarrán and Imbert, Marión, and Ewing

as follows: epithelial and conjunctival tumors. The conjunctival forms comprising sarcoma, leiomyoma, and angiosarcoma are here ignored, but the epithelial forms are further classified into papillary and nonpapillary types. The papillary types are then subdivided into benign papillomas and papillary carcinomas, and the nonpapillary or solid types are subdivided into paramalphigian epitheliomas and epidermoid or cornified epitheliomas. The hardest to distinguish clinically are the two papillary types, the one benign, the other highly malignant, however, in operable cases the treatment is the same —nephrectomy with removal of the entire ureter because of the frequency of implantation into the lower segments of the urinary tract. In the cases of the solid tumors the operation may be limited to the kidney and that part of the upper ureter which is obviously involved. For the nephro-ureterectomy the author prefers the two stage operation.

In the first of the 4 cases here reported the tumor proved to be of a mixed type, a cornified, or pavement cell, epithelioma which diffusely invaded the kidney parenchyma and the perinephric fatty capsule, and scattered fields of a hypemephroid type of large clear cell. However, both types had given rise to more distant metastases, which had retained the identity of the original tumor.

The second tumor was an infiltrating, i.e., a solid, nonpapillomatous epithelioma made up of cells of polymorphous character; however, some areas evidenced a typical malphigian architecture, and the final diagnosis was that of an infiltrating epithelioma of the excretory passages made up of malphigian or atypical cells.

The third tumor, on ascending pyelography, suggested the possibility of a papillary character; however, on operation it proved to be a solidly infiltrating mass, occupying and replacing the entire lower pole of the kidney, and metastasizing in solid masses down the ureter into the perinephric fatty capsule and, in places, throughout the rest of the kidney parenchyma. The tumor cells were highly polymorphic and the presence of polynuclear giant cells rendered the interpretation difficult. At some points the neoplastic tissue had given rise to pseudoglandular structures with a papillary disposition of the tumor capsule. The final diagnosis was atypical and pseudoglandular epithelioma of the excretory passages.

The fourth patient exhibited clinical (cough, hemoptysis) and x-ray evidence of pulmonary metastasis and was not subjected to operation. All of these patients were more than 40 years of age. All had one or more of the usual findings for this condition: pain and tenderness over the involved kidney, hematuria on that side, a depressed contrast urogram and excretion of indigo-carmin (chromo-

ystoscopy), and distortion of the ascending pyelographic image, including the already cited instance in which the confused shadow tones and dentate edges suggested the presence of a papillomatous condition. In no instance did the removed kidney exhibit noteworthy distortion of contour. In not one case did the patient live even 4 months following the operation because of pulmonary or generalized metastases.

JOHN W. BRENNAN, M.D.

Hamm F. C.: Angioma of the Kidney. *J. Urol.*, Balt., 1946, 55: 143.

The patient was a 34 year old infantry rifleman who had been in the service $\frac{1}{2}$ year. He was somewhat "under par" as a result of the severe climatic conditions. His complaints were pain in the back, particularly in the left renal area with typical distribution, radiation anteriorly and downward toward the left testicle. Gross hematuria was observed. The blood was mixed with the urine; it was bright red in color and contained many small clots. No dysuria or frequency was observed, but the record showed that the patient had a temperature of 102 degrees, which responded promptly to the administration of sulfadiazine.

Physical examination revealed a chronically ill male with a sallow color. However, the examination, including abdominal palpation, was otherwise negative.

At cystoscopy bloody spurts of urine were observed coming from the left ureteral meatus. Upon catheterization of the ureters clear urine was obtained from the right kidney, but bloody urine from the left. In the retrograde pyelograms the right kidney was found to be considerably smaller than the left, and, in general, poorly developed. There was also some dilatation of the lower right ureter which suggested the possibility of a previous infection.

The left kidney appeared to be normal in size; if anything, it was slightly larger than normal, but in the upper calyx a small filling defect was observed.

It seemed evident that the lesion was an early neoplasm arising from the epithelium of the renal pelvis, and that under ordinary circumstances this would have been sufficient indication for removing the left kidney and possibly the ureter, but because of the doubtful ability of the right kidney to sustain life, a resection of the upper pole of the left kidney was done.

The specimen consisted of the upper pole of the left kidney, weighing 38 gm. and measuring 16.5 by 3 by 4 cm. The specimen was bisected, which exposed the pelvis and calyces. The usual renal architecture stood out prominently. Immediately contiguous to a papilla of a posterior, superior calyx and apparently arising directly from the pelvic mucosa a small tumor mass measuring about 4 mm. in diameter was found attached to the pelvic mucosa by a broad pedicle.

The mass was dark in color and rough on its superior surface. It was in contact with the sur-

rounding pelvic mucosa, which was somewhat granular, thickened, and of dusky hue. The remaining portions of the pelvic lining revealed no notable alterations, the surface being smooth and pale.

On microscopic examination the tumor appeared as a polypoid mass, the superficial epithelium of which was largely absent and was replaced by a leucocytobemorrhagic exudate in a moderately advanced stage of organization. The pedicle and inferior portion of the mass were covered with transitional epithelium which was continuous with the pelvic epithelium. The stroma was generally dense and fibrous and in places was infiltrated with polymorphonuclear leucocytes including eosinophils. The greater portion of the stroma consisted of widely ectatic vessels resembling a cavernoma.

Many of these vessels were thick walled and fibrous with an endothelial lining. Portions of septa were seen which extended into the lumen as in a cavernomatous mass. Other portions were seen in which the stroma contained an engorged, small, thin walled capillary net. Enlarged dilated vessels were present in the tip of the papilla.

JOHN A. LOEF, M.D.

Squire, F. H., and Kretschmer, H. L.: A Study of the Ureters in Bladder Neck Obstructions. *Radiology*, 1946, 46: 32.

This is a preliminary report dealing with the course of the lower ureters in bladder neck obstruction as observed in intravenous urography. The study is based on a review of 120 films selected at random from the Roentgen Ray Department of the Presbyterian Hospital of Chicago. Since the lower ureters often are not visualized, a rather large number of films had to be examined to find 120 in which their visualization was present.

A normal course of the lower ureters was found in 53 cases (44.16%), 48 (90.56%) of which presented benign obstruction and 5 (9.43%) carcinoma.

In 67 cases (55.82%) the lower ureters had an abnormal course. Of this number, 60 (87.55%) presented benign obstruction and 7 (10.44%) carcinoma.

The following abnormalities were observed:

Right angle turn of the ureter	25
Right angle turn of the ureter (high)	4
Lateral displacement of the ureter	
Marked	7
Slight	2
Looping of the ureter	12
High entrance of the ureter into bladder	4
Low entrance of the ureter into bladder	2
Entrance of the ureter at midline	2
Dilatation of the ureter	
Marked	13
Slight	11
Tortuous ureter	3
Hydronephrosis	6
Normal course of ureter with dilatation	8
Normal entrance of the ureter with lateral displacement	4

T. LEUCUTIA, M.D.

BLADDER, URETHRA, AND PENIS

Coutts, W. E., and Vargas-Zalazar, R.: Contribution to the Etiology of Acquired Fibrosis of the Bladder Neck. *Brit. J. Urol.*, 1945, 17: 136.

The authors state that fibrosis of the vesical neck is characterized by the proliferation of fibrous tissue in the submucosa and into the muscle fibers of the internal sphincter. The entire circumference of the neck of the bladder may be transformed into fibrous tissue, producing a contracture of this structure or only of its inferior portion, sometimes as far back as the trigone; thus a median bar is produced. The disease is congenital or acquired. The acquired form is much more common in adults and is usually confined to the posterior region of the vesical sphincter and trigone. It may arise from trauma, chronic infections of the posterior urethra and prostate, and, in women, from vaginal cervical parametria or perirectal tissues. It is believed that acquired fibrosis is a first stage of submucous and muscle-layer invasion by an infecting agent, and that the virus of lymphogranuloma venereum is the cause in many cases.

Panendoscopy and cystourethrograms are of value in the diagnosis. In the cystogram, the image is similar to that seen in suprapubic prostatectomy.

The authors report 3 cases in which lymphogranuloma virus macroforms in extracytoplasmic plaques were found in tissue removed from the bladder neck with a resectoscope. In their opinion the pathogenic agent invades the bladder neck tissues along the mucous and submucous lymphatics and, based on clinical, laboratory, and histoviral findings, lymphogranuloma venereum virus is a frequent cause of partial or total acquired fibrosis of the bladder neck.

DAVID ROSENBLUM, M.D.

Cristol, D. S., and Brodera, A. C.: Malacoplakia of the Bladder. *J. Urol.*, Balt., 1946, 55: 260.

The cause of malacoplakia of the bladder is unknown. A careful search for acid-fast organisms in the specimens of bladder removed for biopsy in the 2 cases reported by the authors gave negative results. No clinical evidence of tuberculous infection could be found in these cases. *Escherichia coli* was cultured from the urine of both patients.

Grossly or cystoscopically the characteristic lesions appear as plaques which vary in number, size, and distribution. The edges of the plaques appear to be abrupt or slightly overhanging. Very often a zone of hyperemia surrounds these lesions. The centers of the large plaques often appear depressed or umbilicated. Frequently, the epithelium appears to be ulcerated over the center of the lesion.

The principal cellular elements are large oval or polyhedral cells, frequently closely aggregated and found in the submucosa. These cells vary in size, but generally are at least as large as a hepatic cell. They have a well defined cell membrane and are for the most part mononucleated. Often the nucleus has disappeared or its presence is marked by the so-called cell inclusions. While the cytoplasm appears

vacuolated in places, it is most characteristically granular. Within the cytoplasm of many of these cells, as well as between many of the cells, can be seen the Michaelis-Gutmann bodies or "inclusion bodies." These vary in size, shape, and number. In size they range from 1 or 2 microns up to bodies as large as to occupy the entire cell. They have a strong affinity for hematoxylin, which stains them purple. For the most part, they are homogeneous and highly refractile. The smaller forms are round or oval; the larger forms show fine crenations or irregularities. Many of them show a definite concentric lamination suggesting corpora amylacea. When stained with the Kossa stain they reveal a high calcium content.

The majority of the patients are women more than 30 years of age who give histories of having suffered frequent bouts of cystitis. However, all age extremes in both sexes have been described.

Urinary frequency and gross hematuria are the most prominent symptoms. The diagnosis rests on the finding of the characteristic lesions and the removal of a portion of the diseased tissue for microscopic examination. The microscopic picture, as previously described, establishes the diagnosis.

The cases of malacoplakia so far reported are too few for the treatment to be standardized. The authors agree with Blum, Folsom and Dickson, Gray and Kidd, in reporting fairly good results following fulguration.

Cordonnier, J. J.: Fistula of the Penile Urethra. *J. Urol.*, Balt., 1946, 55: 278.

The subject of fistula of the penile urethra has assumed added importance since the advent of the present war. Plastic repair of this condition has always presented considerable difficulty, and numerous plastic procedures have been recommended for the purpose of repairing this defect. Although stainless steel "pull out" sutures have been widely used in other locations, no mention of their use in this connection has been found in the literature. A series of 3 cases is presented for consideration. Good results were obtained in all of these cases, with prompt healing of the operative wounds, without infection, and it is believed that the method described is superior to the methods previously presented.

The use of sulfadiazine and penicillin in combination, both preoperatively and postoperatively, has undoubtedly played a very important role in the successful conclusion of these cases. Infection has always been the principal problem in a repair of this nature and, by the use of these two drugs in combination, is practically eliminated. All 3 cases healed without any signs of wound infection.

Diversion of the urinary stream is an essential step prior to operation. It is believed that a suprapubic cystostomy is preferable to perineal urethrostomy. The presence of repeated nocturnal erections, which seemed to be due to irritation of the posterior urethra by the catheter, presented a definite hazard to the success of both operations when an external

urethrostomy had been done. Although urethrostomy is a much simpler technical procedure, the additional operative work required by cystostomy is warranted for this reason alone. Drainage of the bladder by urethral catheter, with the inevitable accompanying urethral infection, is contraindicated.

It is believed that simplicity of procedure is an important factor in any plastic procedure for the repair of urethral fistula. The use of scrotal flaps, skin grafts, and other complicated procedures are generally unnecessary, and only serve to add additional hazards to obtaining a successful result. A careful elevation of the skin flaps around the incision will ordinarily allow closure of the wound without tension.

Careful handling of tissue is undoubtedly important in any plastic repair of this nature. To minimize trauma, small hooks are used throughout, instead of thumb forceps. Plain catgut (0000) on an atraumatic needle is used for all sutures except the skin. The use of the No. 36 stainless steel wire "pull out" suture is probably the most important single step in bringing about a successful closure. It permits the use of finer catgut than would be possible otherwise. The advantage of fine catgut in a potentially infected area is self evident. In addition, all tension is removed from the suture lines.

The use of a pressure dressing to prevent the formation of hematoma under the elevated skin flaps is advisable in certain cases. Meticulous wound care must be observed at all times. The topical use of 1300 penicillin as a urethral instillation has been of value. Periodic urethral dilatations must be maintained for a period of time to prevent stricture formation.

A method of repair utilizing stainless steel "pull out" sutures is described. The procedures outlined are simple to perform. Postoperative convalescence is short and the results have been excellent.

JOHN E. KIRKPATRICK, M.D.

GENITAL ORGANS

Borthwick, W. M.: *The Pathogenesis of Tuberculous Epididymitis*. *Edinburgh M. J.*, 1946, 53: 55.

Borthwick studied the pathogenesis of tuberculous epididymitis by examining the records of 5,476 tuberculous males admitted to the hospital during a period of 21 years, and 402 (7.3%) had involvement of the epididymis by tuberculosis. The corrected true incidence is probably 4.5 per cent. The youngest patient was 8 months old and the oldest was 63 years old.

Male genital tuberculosis occurs most commonly during the years of maximal sexual activity. In 88.3 per cent of the patients at least one extragenital tuberculous lesion was proved. Injury appears to have little influence in the production or localization of the genital disease. Gonococcal epididymitis had little or no influence on the occurrence of tuberculous epididymitis. The lesion was unilateral in 43.5 per cent of the patients and bilateral in 56.5 per cent.

Recurrence occurred within 1 year in 74.6 per cent, and in 58.7 per cent the disease became bilateral within 6 months. Negative rectal findings were present in 12.7 per cent. The remainder (87.3%) were "rectal positive." The author received the impression that, no matter how early the tuberculous epididymitis, a lesion of the pelvic genitalia could be felt rectally in the great majority of patients, and that vesiculitis or prostatitis, or both, precedes the more peripheral genital lesion.

Renal tuberculosis also was present in 34.8 per cent of the patients. Men with epididymal tuberculosis in whom tubercle bacilli cannot be isolated from the kidney urine are extremely few in number. The author believes that renal tuberculosis precedes epididymal tuberculosis in the great majority of cases. Tuberculous prostatitis and vesiculitis precede epididymitis; *the globus minor is the first part to be affected, and in testicular disease the maximum involvement was at the mediastinum testis.*

The author is satisfied that the sequence of events in genitourinary tuberculosis is from the kidney to the pelvic genitalia and from there to the epididymis. The spread of tuberculosis to the epididymis takes place in the majority of cases by the lumen of the vas deferens. The great majority of patients with tuberculous epididymitis have or have had a tuberculous bacilluria from a clinical or subclinical lesion of the kidney. In almost every case of tuberculous epididymitis in the present series, with or without urological symptoms, tubercle bacilli have been isolated from the kidney urine. Infection of the prostate and seminal vesicles probably takes place by urine transmission, by heavy work, straining, and the very act of micturition. DAVID ROSENBLUM, M.D.

Mansfield, O. T.: *Spontaneous Gangrene of the Scrotum (Fournier's Gangrene)*. *Brit. J. Surg.*, 1946, 33: 275.

Mansfield reports a case of spontaneous gangrene of the scrotum in a man 43 years of age who was admitted to the hospital with an entirely gangrenous scrotum. This was removed, except for 3 triangular flaps at the base which seemed to retain viability. Two of these were based laterally and 1 posteriorly, and between them both testes lay completely exposed. Section of the removed tissue showed marked interstitial edema with many thrombosed vessels. The patient's condition rapidly improved after operation, and epithelization was complete in 6 weeks.

Fournier first described the condition in 1844, noting the explosive onset in a healthy man, the rapid progress of the gangrene, and the total absence of the usual causes for gangrene. Further reports in the literature describe the extensive and fairly constant area of gangrene with integrity of the testes and inguinal and anal regions, rapid resolution of the adjoining cellulitis, and a tendency for spontaneous repair.

The author believes that the condition is a vascular disaster of infective origin analogous to cavernous sinus thrombosis. The fairly constant pattern of the

sloughing area is adequately explained on a vascular basis which would account for the existence of the described flaps. The latter are supplied by the external pudendal branch of the femoral artery and superficial perineal arteries. The rapid gangrene is comparable to that of a flap of skin which has become infected and its limited vascular supply destroyed by thrombosis. Therefore, treatment should consist of radical removal of all sloughing areas, sulfonamides, and penicillin. Repair seems unnecessary. Reports in the literature indicate that death in most instances has been due to toxemia. The bacteriological agents have been streptococci, staphylococci, or both.

DAVID ROSENBLUM, M.D.

Bertelsen, A., and Wandall, H. H.: Vaso seminal Vesiculography and Its Clinical Application. *Acta radiol.*, Stockholm, 1945, 26: 36.

Following a brief résumé of the literature on vesiculography, the authors report 16 of their own cases in addition to some work on rabbits to show the irritative effects of hippodin (a 50 per cent solution of sodium orthiodine hippurate) as compared to the innocuous preparation, perabrodil (3,5-diiodide-4-pyridon-N-diethyl-amine acetate).

The experimental work showing the irritative qualities of hippodin was done on the vasa of rabbits which were injected close to the testicle and sections of the vasa were removed at 2, 4, 10, 14, and 21 day intervals for microscopic study. On the second day the vasa injected with hippodin showed round cell infiltration, especially eosinophilia in the wall of the vas, whereas the epithelium of the vas was well preserved everywhere. The specimens of the fourth day showed complete epithelial desquamation and slight submucosal fibrosis, and by the fourteenth day there were no pathological changes. On the other hand, the rabbit vasa injected with perabrodil showed no changes at anytime from 2 to 28 days after injection.

Of the 16 patients subjected to vesiculography, 6 were examined at vasectomy and 10 were examined for diagnosis of genital diseases. The conditions found were as follows:

Aspermia (1); oligospermia (1); groin and testicular pain following herniotomy (2).	4
Aspermia following testicular trauma.	1
Sequel of epididymal resection	1
Undescended testicle.	2
Vesiculitis.	2

In 3 cases of herniotomy by the Bassini method there was obstruction to the vas where it entered the inguinal canal. In the 2 patients with undescended testicles the vas was extraordinarily tortuous, but no variation in vasa caliber was evident. In the 2 instances of operatively proved seminal vesiculitis there was no evidence of dilatation of the canals nor retention of the contrast media. In 3 instances (1 with undescended testes, 1 with trauma to the testicle, and 1 with an epididymectomy with an infection) there was demonstrated an insufficient development of the seminal vesicles and this the authors explained on the basis of disuse.

In the opinion of the authors, the use of vesiculography for diagnostic purposes is warranted by the following:

1. Aspermia in the presence of preserved testicular function.
2. Seminal vesiculitis
3. Adults (not children) about to have an orchidopexy to reveal the presence of sufficient length of the vas deferens
4. Patients with groin or testicular pain following herniotomy with the vesiculogram demonstrating the presence or absence of constriction of the vas at the operative site.

ROBERT LICH, JR., M.D.

MISCELLANEOUS

Moore, T.: True Infective Abacterial Pyuria. *Brit J Urol.*, 1945, 17: 131.

The author describes "true infective abacterial pyuria," a syndrome which has been experimentally transmitted to animals and apparently caused by a virus infection. The mucosa of the posterior urethra, bladder, or upper urinary tract is affected. The infection resists all forms of treatment except intravenous arsenobenzole drugs. In the renal pelvis the mucosa is thickened and edematous; it shows varying degrees of erythema, and flakes of lymph adhere to it. The submucosa is infiltrated with mononuclear cells, sometimes aggregated into follicles. No organisms are seen. There is no disease of the renal substance. The onset is acute or gradual. There is frequency, dysuria, and sometimes hematuria, with little or no disturbance of the general health. The urine contains many leucocytes, but microscopic examination and culture fail to demonstrate organisms.

Intravenous urography shows some dilatation of the pelvis and ureter, and sometimes small filling defects due to follicular pyelitis and ureteritis. Cystography shows a tiny contracted bladder with an irregular outline. Cystoscopy shows generalized severe nonspecific inflammatory changes, with none of the characteristic appearances of urinary tuberculosis. Tubercle bacilli are never found. There are no constitutional changes, no loss of weight, and no urographic evidence of renal damage. In doubtful cases the therapeutic test is of value.

The course of abacterial pyuria is prolonged and the bladder capacity becomes progressively reduced. The administration of an organic arsenic preparation, such as novarsenobenzole, causes rapid improvement and cure. The author usually administers .3 grams intravenously at intervals of from 5 to 7 days. Normally, four doses are sufficient. A case report is given.

Flocks, R. H.: "Early" Calcium Urolithiasis. *J. Am. M. Ass.*, 1945, 130: 913.

It has been shown that calcium urolithiasis is likely to occur in conditions in which immobilization of the individual is present, in which portions of the

TABLE I.—PREVENTIVE TREATMENT OF CALCIUM PHOSPHATE UROLITHIASIS IN PATIENTS WHO ARE EXTENSIVELY IMMOBILIZED OVER LONG PERIODS OF TIME

Measures	Accomplishes	Comment
1. Maintenance of large fluid output	a. Counteracts stasis by producing a steady flow of urine b. Diluted calcium concentration especially important during period of hypercalcinuria (first 6 to 12 weeks of immobilization) c. Minimized likelihood of infection d. Washes out debris and small calcium precipitates	a. Measure intake and output carefully; remember in cases of neurologic involvement that residual urine may cause inaccuracy in output measurement
2. Control of diet High vitamin A and B acid ash diet usually used	a. High vitamin A and B improve epithelial nutrition b. Increase acidity of urine; calcium phosphate is more soluble in an acid than in an alkaline urine	a. Check urinary pH daily with nitrazine paper b. Discontinue acid ash diet if urine remains alkaline from any cause such as infection with urea-splitting organisms
3. Control of stasis a. Movement of patient b. Provision of adequate drainage by catheter or surgery if necessary c. Maintenance of a large fluid output	a. Makes sure that no portion of urinary tract is dependent or undrained for too long a time b. Minimizes infection c. The use of a catheter makes possible irrigation of pelvis or ureter with special solutions such as citric acid and malic acid solutions	
4. Control of infection a. Maintenance of large fluid output b. Adequate drainage c. Chemotherapy: 1. Sulfacetimide 4 gm. daily in drug of choice 2. Sodium sulfathiazole 4 gm. daily 3. Other sulfonamide 4. Neosarsphenamine 0.3 gm. two times weekly in some staphylococci infections 5. Penicillin, very useful	a. Decreases particles in urine (pus and epithelial debris, which may act as nuclei for stone formation) b. Infection with urea-splitting organism produces alkaline urine, which causes precipitation of calcium phosphate	a. Watch urine pH with nitrazine paper b. Study centrifuged urine specimen daily for pus cells
5. Continuation of treatment for 3 months after immobilization has ceased	To remove any small precipitation which may have formed during period of stasis and hypercalcinuria	
6. Frequent radiographic check-up examinations during illness and every 3 months for one year after immobilization has ceased	This is very important; small precipitates may not be visualized in early urograms but may be visualized later after they have grown; many stones (especially in patients with neurologic lesions) may be silent for years and thus produce irreparable damage unless they are visualized by x-ray examination and treatment instituted	

Note: Henline has shown that the emptying time of the renal pelvis is greatly increased by a small urinary output and decreased by a large fluid output (Lowsley and Kirwin. Clinical Urology).

urinary tract are paralyzed, and in which obstructions and infections of the urinary tract occur, or in which pronounced dehydration is present. There are three probable mechanisms involved in the formation of stone in these situations: infection, stasis, and hypercalcinuria. Multiple small precipitates of calcium phosphate are present in the calices and pelvis of the kidney. These small stones may all pass; they may fuse to form larger stones, or may act as the

nucleus for larger stones; and they may be silent for long periods of time, during which considerable damage to the urinary tract occurs. In the first 6 or 8 months after the onset of the predisposing conditions, before the stones have become intimately mixed with organic material and definitely solidified, the situation may be called "early" calcium urolithiasis. Because this condition is frequently silent, repeated roentgen examinations are necessary.

TABLE II.—CONDITIONS PREDISPOSING TO CALCIUM PHOSPHATE UROLITHIASIS

1. Disease producing prolonged immobilization of the body:
 - a. Fractures of the spine or extremities associated with prolonged immobilization of large bones.
 - b. Chronic osteomyelitis
 - c. Chronic arthritis or other bone joint disease producing immobilization of large portions of the skeleton
 - d. Neurologic damage as a result of trauma or disease producing prolonged immobilization
 - e. Chronic visceral disease requiring prolonged recumbency
2. Changes in the urinary organs:
 - a. Congenital anomalies associated with stasis
 - b. Acquired obstruction—stricture of urethra and the like
 - c. Paralysis of urinary passageway
 - d. Introduction of infection into urinary tract
 - e. Foreign body in urinary passageway
3. Endocrinopathies:
 - a. Hyperparathyroidism
 - b. Hyperthyroidism?
 - c. Hyperpituitary disease?
4. Focus of infection elsewhere in the body?
5. Vitamin deficiency or excess
 - a. Vitamin A deficiency?
 - b. Vitamin D excess
6. Metabolic abnormalities
 - a. Idiopathic hypercalciuria
 - b. Changes in colloids?

Note: Conditions with question mark are put in mainly on a theoretical basis. Others are put in on the clinical basis.

Special types of treatment are necessary because of the peculiar character of these stones. Later symptoms may be hematuria, ureteral colic, infection (due to stone obstruction) resulting in pyuria, chills, fever, leucocytosis, and renal pain.

When infection is not present and no renal damage has yet occurred ("early phase"), the stone is ideal

for dissolution by means of a combination of fluids, diet, and irrigation therapy. When infection commences, the stones grow more rapidly, calcium phosphate precipitates in the tubules, and the tips of the pyramids become ulcerated and sometimes calcified. If adequate drainage cannot be instituted by ureteral catheter, open surgery must be done. In addition, supportive treatment, chemotherapy, and irrigation should be carried out. In chronic cases the kidney pelvis and calices become distorted from infection, which results in a disturbance of peristalsis, poor drainage, and ready recurrence.

When a case is seen early, there is a typical irregular opacity suggesting depositions of calcium salts usually around the pyramids in the calices. When severe infection is present, there is evidence of consolidation of the calcium particles into definite stones, and dilatation of the kidney pelvis, infection, and obstruction. In late cases the stone shadows are much more dense, there are extensive changes in the calices, kidney pelvis, and kidney, and the condition has passed to the state of late calcium urolithiasis.

With regard to treatment, the author states that because the stone in early calcium urolithiasis is soft and mushy, surgical measures usually fail. If consolidation has not occurred, irrigation therapy through a ureteral catheter, double ureteral catheter, nephrostomy or pyelostomy tube, with acetic acid solutions, citrate solutions, citrate solutions with magnesium oxide, malic acid solutions, and solutions containing proteolytic enzymes, will usually break up the particles and cause them to pass. Infection is controlled by sulfathiazole, penicillin, fluids, and adequate drainage. Open operation is contraindicated in early calcium urolithiasis, until irrigative treatment has been given a thorough trial, and, if open operation is performed, postoperative irrigation through a pyelostomy or nephrostomy tube is of value.

DAVID ROSENTHAL, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

hrom, S. A.: On the Incidence of Osteochondrosis. *Acta radiol.*, Stockh., 1945, 26: 49.

In cases of osteochondrosis the roentgen examination of the lumbar spine shows a characteristic narrowing of some intervertebral disc, most often the 5th lumbar. It is accompanied by osseous changes in the form of sclerosis of the borders of the vertebral bodies involved and typical exostosis formation on the anterior border of one or both of these bodies. In some cases this finding is complicated by a displacement of the two bodies in relation to each other, which gives the appearance of spondylolisthesis. These changes are typical of osteochondrosis.

The process begins with a diminution of the fluid content of the nucleus pulposus, and later the x-ray shows cracks and fissures running in all directions. As the process progresses the nucleus shrinks and the size of the disc diminishes. The annular fibrous ring remains intact, although the fibers of the ring become slack, and thus the possibility arises for the vertebral bodies to become slightly dislocated in relation to each other. To the continuous small traumas to which their surfaces thereby become exposed, they react by sclerosis. All of the secondary changes here described may not be found in all cases. A diminished disc as the only finding is of no value whatever, especially in the case of the 5th lumbar disc, because normal variations in the shape and position of the 5th lumbar vertebra vary considerably. In young individuals spondylolysis deformans may be present. This disease shows degeneration in the peripheral part of the disc and the fibers of the annular ring. The fibers break, the disc bulges outward, and there is pressure on the anterior longitudinal ligament. A beak-shaped exostosis develops, distinguished from the exostosis which develops in uncomplicated cases of osteochondrosis. The differential diagnosis rests between acute and chronic inflammations and malignant tumors, but in these cases there is a marked thinning of the bone due to the loss of calcium salts.

One hundred and thirty-two patients were used for this study. In 20 of the cases there was a characteristic picture of osteochondrosis. In 18 of the 20 cases the location of the lesion was in the 5th lumbar disc; 11 of the 20 patients were men. Twelve of the 20 patients were between 40 and 59 years of age. Fifteen of the 20 had been admitted to medical services for various reasons. One often sees marked spondylolysis deformans associated with very few symptoms. A control group of 63 patients was studied. Two of these patients showed typical findings of osteochondrosis. In patients with complaints referable to the vertebral column, frequency of osteochondrosis is ten times greater than in the controls.

The characteristic roentgenological changes in cases of osteochondrosis were: (1) narrowing of the disc and marginal sclerosis in all 22 cases; (2) lip-like marginal exostosis in 19 cases; and (3) displacement of the bodies of the vertebrae in relation to each other in 6 cases. In 4 of the 6 cases of displacement, the body of the upper vertebra had slid forward, and in the 2 others it had become displaced backward. In these 6 cases the other three characteristics were present. Air myelography was done in 7 of the 20 cases in which there was osteochondrosis. In all 7 cases the findings were positive, and in 6 of the 7 cases the findings were verified at operation. Only by air myelography is it possible to ascertain whether a prolapse of the nucleus exists.

RICHARD J. BENNETT, JR., M.D.

Einarsson, F.: On the Treatment of Dupuytren's Contracture. *Acta chir. scand.*, 1946, 93: 1.

The author reviews the literature from the earliest description of Dupuytren's contracture by Sir Astley Cooper in 1822, to the present time, and tabulates cases to show the preponderance of males with either right hand or bilateral involvement.

The pathological change is in the palmar aponeurosis where increased vascularization and round cell infiltration in proliferating connective tissue gives way, in time, to a tendonlike cord, and gradual contracture of this cord causes severe flexion deformity of the fingers usually on the ulnar side of the hand. Deep extension of the process may surround the vessels and nerves, but the flexor tendons themselves are never included in the pathological process. Subcutaneous fat and, sometimes, palmar skin degenerate into this fibrous tissue. (Plantar fascia may be similarly affected, and the lesion is localized to the tibial portion of the aponeurosis.)

Many surgical procedures have been advanced to offer relief to the patients. All have been directed toward excision of all or part of the palmar aponeurosis, division of the palmar aponeurosis, or digital amputation. Various types of procedure are outlined, and several palmar approaches are illustrated. The consensus of opinion is that incision must be adapted to the individual case, but should, as nearly as possible, follow the palmar creases. Great care must be taken to avoid injury to the embedded vessels and nerves which may be widely displaced.

The prognosis must be guarded as to recurrence, which is frequent, and tender or insensitive fingers may be handicapping in the absence of recurrence.

During a period of 16 years in the Orthopedic Hospital in Copenhagen, 164 hands of 111 patients were treated for this condition. The cases were classified according to Meyerding's grading, and a total of 84 hands were operated upon. The surgery performed was partial excision of the palmar aponeurosis and/or digital amputation.

shoulder equalled that of the opposite one in 5 patients and was reduced but good in the other five.

The 7 patients whose ruptures were sutured had longer hospitalization, from 5 to 10 weeks, and returned to work in from 2 to 5 months postoperatively. The range of motion and strength of shoulder were similar to the former group, and the patients had no pain. In each group a single patient developed an arterial fistula which closed spontaneously in 3 weeks.

The advantages of simplicity of operation, avoidance of prolonged immobilization, and early return to work, with relief of pain and improvement of both the mobility and strength, recommend this method of treatment.

FRANCES E. BRENNCKE, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Boppe, M. and Leroy, M.: Results of Stabilizing Operations on the Bones in Paralytic Feet, with or without Transplantation of the Tendons (Résultats des opérations de stabilisation osseuse sèches ou associées aux transplantations tendineuses dans le traitement des pieds paralytiques). *Rev. chir.*, Par., 1945, 64: 145.

The authors report on 78 cases of stabilization of the bones in paralytic feet, discussing the technique of the different operations in detail, and giving the indications, the causes of failure, and the final results.

The best age at which arthrodesis or arthroereisis should be done is between 12 and 13 years. At this time the chances of obtaining good ankylosis are best, and there is little danger of secondary deformity caused by abnormal pressure and muscular traction during the growth of the bones. Under the age of 9, arthrodesis is strictly contraindicated.

The failures consist in fibrous pseudarthrosis, fracture of the bone grafts, or secondary deformity.

In 22 of the 78 cases, transplantation of the tendons was done in addition to the bone surgery, partly at the same time, and partly some months after the arthrodesis. The last method gave the best results.

The detailed discussion of the various surgical procedures should be read in the original article.

WERNER M. SOLMITZ, M.D.

FRACTURES AND DISLOCATIONS

Do Amaral, A. C.: The Treatment of Fractures of the Neck of the Femur by the Brazilian Method of Godoy Moreira—Extra-Articular Nailing (Tratamento das fraturas do colo do fêmur pelo método brasileiro de Godoy Moreira—aparafusamento extra-articular). *Rev. méd. Municipal*, 1945, 6: 245.

This article includes an extensive review of the problem of femoral fractures, with special consideration of those involving the femoral neck, and describes the treatment evolved by Godoy Moreira.

Fig. 1. At left are seen the two varieties of medial fractures of the femoral neck: In valgus, with the angle greater than 130 degrees; in varus, with an angle less than 130 degrees. On the right is seen the lateral type.

The author presents a general description of the anatomy, development, architectural features, and lines of stress associated with fractures of the neck of the femur.

Discussing the vascular supply of the upper portion of the femur, the author quotes the work of Zarzaga. He concludes that the blood supply to the hip joint and upper portion of the femur is maintained by an anastomosing arterial plexus derived ultimately from the profunda femoris and the internal iliac arteries. This includes branches direct to the bone, as well as the artery of the round ligament.

Fractures of the upper femur are discussed in the light of their classification by several methods. The author prefers to classify fractures of the neck as medial and lateral. The medial fractures may be in valgus or varus (Fig. 1). The medial fractures are difficult to hold in reduction and, therefore, offer a more serious prognosis, particularly when in varus as they then require surgical fixation. Lateral fractures are much easier to maintain in reduction and offer a better prognosis. Immobilization in plaster is frequently the treatment of choice.

Fractures of the femoral neck constitute approximately 40 per cent of femoral fractures and of these, according to the author's classification, the lateral type is the most frequent, and the medial type in varus is next in the proportion of 4 to 1. The medial type in valgus is relatively rare.

The mechanism of these fractures is discussed. The symptomatology is developed in some detail. The symptoms and signs common to all types of fractures of the femoral neck are dysfunction, attitude of the member, pain, deformity of the inguinal fold (Laugier's sign), shortening (8 measurements and methods of measurement are described), hydrarthrosis of the knee, ecchymosis, and edema of the base of the coccyx. The medial type of fracture, complete and not impacted, which is the usual type, completely prevents active motion and extreme external rotation; shortening is immediate, Laugier's sign is present, and the inguinal mass is well medial; spontaneous pain is not very marked, but pressure on the femoral head and passive motion are painful. When impacted, some active motion is usually pos-

Fig. 2. Position of the patient, x-ray tube, cassette and projections of the femur; at left, A-P projection; center, the lateral projection; at right, the "lithotomy" position.

sible; Laugier's sign is not marked, nor is the shortening pronounced.

In the lateral type with impaction, which is the rule, movement is possible. The member is externally rotated; the thigh and knee are semiflexed and usually the thigh is adducted, although abduction is seen; shortening is pronounced; Laugier's sign is present and lateral in position; spontaneous pain is not great, but pressure over the greater trochanter and passive motion are very painful.

Prognostically considered, fractures of the femoral neck result in (1) bony union in anatomical position, (2) bony union in poor position, (3) bony union with or without accompanying arthritic changes, and (4) pseudarthrosis. The medial type of fracture, particularly in old persons, offers a poor outlook for a completely satisfactory result when managed by current methods. Lateral fractures, however, result in a satisfactory outcome consistently. A pseudarthrosis in this type is exceptional.

The complications occurring in patients with the lateral fracture include fat embolism, intra-articular suppurative, phlebitis, urinary retention, decubitus ulcers, and, finally, lung involvement.

The complete diagnosis of these lesions requires use of the x-rays. Not only are they required for accurate determination of the presence of fracture and its type, but also for control of the operative procedure. The x-ray views should include the anteroposterior, the lateral in position of reduction, and the lateral with the patient in the lithotomy position (Fig. 2).

The treatment of these fractures according to the author's classification can be summarized as follows:

1. Medial fractures in valgus are to be treated operatively in the aged and by simple extension in the young.

2. Medial fractures in varus are to be treated operatively regardless of age.

3. Lateral fractures are treated in plaster in the young and in the older patient who is in good general condition. In old patients in poor condition, operative intervention is indicated. (Children are not considered in this discussion).

An exhaustive description of the various methods of treatment and a summary of the results accompanied by illustrations are given. The methods discussed include that of Lucas Championniere; continuous extension; and immobilization in plaster, by bone graft, by osteotomy, by resection and ankylosis, and, finally, by metallic extra-articular fixation.

The method of Godoy Moreira, in summary, follows:

After the fracture is reduced under roentgenographic control, a 10 cm. incision down to the bone is made at the level of the greater trochanter. The muscle mass is separated in order to visualize the lower aspect of the trochanter (called the innominate tubercle) which serves as a guide for the procedure. At this point a small initial defect is made in the bone. The direction of the femoral head and neck is obtained by using the standard anatomical landmarks, aided by a metallic centimeter ruler placed over the anterior upper thigh in the presumed direction of the femoral neck. This ruler is included in the postreduction roentgenogram. A Kirschner wire is then introduced with an electric motor; however, it is finally driven to contact the cortex of the femoral head by the use of a hammer. An 11 mm drill is used to tunnel the greater trochanter in order to accommodate the locking shaft of the apparatus later. The tunnel through the neck is completed with a 6 mm. drill so as to receive the body of the

Fig. 3. Final roentgenographic control before and after the impaction.

screw. The drills and the screw are hollow and are threaded over the Kirschner wire as a guide. The fragments of the fracture are finally impacted with the locking shaft and counter screw. (The wire is removed after the introduction of the screw.) The fragments are held immobilized during the procedure by a special lever held by an assistant against counter pressure on the pelvis by still another assistant.

The author has introduced some modifications in the method, and the patients are managed along the following general lines:

The diagnosis of fracture having been made and surgical intervention having been decided upon, the patient is placed in light traction in extension, abduction, and internal rotation for a period of from 8 to 10 days. The Hawley-Scanlan orthopedic table is employed but modified by being divided into two longitudinal halves, presumably displaceable but no longer than sufficient to reach the patient's knees, so

that the x-ray tube may be brought up between the knees for taking the lateral roentgenogram. The pelvic support is made of wood. A means of rapid film development is used. General anesthesia is not employed.

The fracture is then reduced. With the anatomical landmarks as a guide, a Kirschner wire is introduced with an especially designed electric motor, for a distance of from 4 to 6 cm. only. Roentgenograms are then taken in anteroposterior and lateral projections to determine the adequacy of the reduction and the direction of the wire. If the direction of the wire is not satisfactory, another is similarly introduced with the necessary correction, without removal of the first. The proper screw is then selected, and the Kirschner wire is taken as a measure, since it is of known length (30 cm.). The area of the wire is then laid open by a small incision down to the bone. An 11 mm. drill is then used to tunnel the cortical bone for a distance of 2 cm. The screw is

INTERNATIONAL ABSTRACTS OF SURGERY

then passed over the wire as a guide and set into the head of the femur without further preliminary drilling. The locking shaft and counter screw are then set, the fragment being impacted as desired. A roentgenographic check is made again. No immobilization is used postoperatively. Active and passive motion, as well as sitting, is begun promptly. Walk-motion is delayed from 45 to 60 days.

Later experience suggests that a Kirschner wire can be fixed to the skin of the thigh in the proper direction of the head and neck, as determined by fluoroscopic control, and then the transfixing wire can be introduced, this wire being used as a guide in association with lateral fluoroscopic control. An additional wire is recommended even if it is demonstrated that the first is correctly placed, in order to prevent rotation or slipping of the fragments during the subsequent steps.

Twenty-four cases have been treated by this method and 6 others by means of the Smith-Petersen nail. Twenty-seven of the cases were medial type fractures in varus, 2 were lateral, and 1 was a pseudarthrosis of a year's duration. The patients ranged from 28 to 85 years of age. Twenty-one of the 30 cases resulted in excellent bony union; 3 developed pseudarthroses (these were considered poor results); 1 other case developed pseudarthrosis, but was classed as having a good result because the screw permitted walking. The results in 2 cases cannot as yet be evaluated (5 months). On patient died; 2 patients did not tolerate the screw, requiring its removal in 8 and 75 days, respectively. The latter patient eventually succumbed to cardiorenal disease. Associated diseases in these patients have often been serious.

HIAAM T. LANGSTON, M.D.

Hampton, O. P., Jr.: Delayed Internal Fixation of Compound Battle Fractures in the Mediterranean Theater of Operations. *Ann. Surg.*, 1946, 123: 1, 238.

This article, written in two parts, presents a follow-up study and evaluation of the treatment of 332 compound battle fractures treated in the Mediterranean theater of operations by delayed internal fixation. Plates, screws, and wire were the modalities of internal fixation employed. Part I describes the procedures, statistics, and conclusions. In Part II 20 case reports with illustrations are provided to demonstrate the problems involved.

The use of delayed internal fixation in the Mediterranean theater of operations began in April, 1944, and the great majority of the operations were performed between June 4, 1944 and November 1, 1944. The operations were performed in 18 base hospitals by approximately 50 surgeons. The information for this report was gathered by the author between March 16 and April 26, 1945 and represents a follow-up period of less than a year for the majority of the cases. Twenty-four Army general hospitals located throughout the United States were visited during this 6 weeks and 300 complete case reports were assembled. Thirty-two additional patients were

located as on duty, demobilized, or in convalescent hospitals, and this status was considered as reasonable assurance that the results were very satisfactory. Although not specifically stated, it is presumed that the report covers all the compound battle fractures treated by delayed internal fixation during the dates mentioned. No comparison is made in this article between the results in these cases and similar data for groups of battle fractures managed without the use of delayed metallic fixation.

Initial surgery as compared to reparative surgery is the excisional phase which is designed to save life and limb and prevent infection. It is performed in the combat zone as soon after wounding as is feasible. Reparative surgery is performed in a base hospital from 5 to 10 days after wounding and the routine procedure for compound fractures is as follows:

The operating room is set up for any possible indicated surgery on a compound fracture. The patient is properly prepared and is anesthetized in the operating room, where the encasement and dressing which had been applied after initial surgery are removed. The extremity is cleansed, prepared, and draped. The wound is visualized thoroughly by gentle traction. Any residual dead tissue is excised and the depths of the wound are cleansed of all blood clot. The fracture site is exposed. It is there and then that internal fixation may be employed as part of the first procedure of reparative surgery and its advantages are obvious, e.g., in condylar fractures of the joints, oblique fractures of the long bones which are easily reducible, or segmental defects due to bone loss. Wound closure, usually with drainage, completes this stage of reparative surgery. In the great majority of cases, reduction is attempted by traction or manipulation. If adequate reduction is not achieved and the contour of the fracture persists, internal fixation may be performed at another operation, perhaps after wound healing. Internal fixation was not reserved for the ideal case but was employed frequently in fractures that would be major problems under any plan of management.

The advantages of delayed rigid internal fixation in the management of a compound battle fracture are: (1) Optimal apposition and alignment; (2) elimination of the dead space of an unreduced fracture, and its attendant traumatizing manipulations; (3) early joint motion and muscle exercise may be permitted; (4) multiple operating room procedures for concurrent injuries are permitted; and (5) staged procedures for the compounding wound are facilitated. The disadvantages of delayed internal fixation in these injuries may be stated as follows: (1) any periosteal stripping incident to the open reduction and placement of the metal potentially devitalizes the denuded cortex of bone; (2) the extent to which the metal interferes with the reattachment of soft parts to denuded bone enhances the chances of sequestration; and (3) the trauma incident to the fixation, retractor pull or vessel ligation, may devitalize the soft tissue and thereby establish a nidus for wound sepsis.

The indications for delayed internal fixation were divided into three groups: obligate, desirable, and elective. The obligate group was again divided into 5 groups: (1) bone loss producing a segmental defect or persistent distraction, in either of which nonunion is almost inevitable; (2) inadequate reduction by nonfixation measures, skeletal traction, "hanging cast", or manipulation; (3) condylar fractures at the knee or elbow; (4) massive loss of soft tissue which demanded repeated staged procedures and preferably a fixed fracture; and (5) associated nerve trunk injuries, the optimum management of which required fracture fixation. The desirable indications varied with the bone involved and all fixations were performed at the first operation of reparative surgery as follows: the femur was rigidly stabilized with plates or screws in the nonobligate group; the tibia and fibula were rigidly stabilized with screws only in the nonobligate group; the radius and ulna were subjected to all types of fixations in the nonobligate group. No indications were classified as desirable among the fractures of the humerus. For the elective indications, all fixations were done at the first operation of reparative surgery. These included all wire loop fixations of the femur in the nonobligate group; all platings (including those of the fibula) and wire loops of the tibia and fibula in the nonobligate group; and all types of fixation of the humerus in the non-obligate group.

The results of delayed internal fixation were classified into 6 groups summarized as follows:

Result A. Union of the fracture and wound healing without sequestration or removal of the metal.

Result B. Union of the fracture, and, following removal of the sequestra and metal, wound healing.

Result Ba. The same as B but the sequestration was massive, so as to prejudice the strength of the bone.

Result C. Union of the fracture but no wound healing; however, in many cases the metal and sequestra were not removed.

Result D. Union of the fracture and wound healing after removal of the metal and sequestra, but the time required for each was prolonged appreciably.

Result E. Nonunion of the fracture but wound healing without sequestration or removal of the metal.

Result F. Nonunion and sequestration without wound healing (in 5 cases the wounds healed after removal of the sequestra and metal).

Detailed statistical tables of data are compiled to show: (1) results in relation to the type of fixation, (2) results in relation to the indications, and (3) a summary of all results: (a) those not classed as excellent and (b) those not very satisfactory.

Each of the 25 cases with the F type of results is abstracted and an appraisal of them is offered by the author: (1) improvement following fixation, 2 cases; (2) no improvement, but healing not retarded, 8 cases; (3) healing retarded, 13 cases (3.9% of 332 cases); and (4) not classifiable at this time, 2 cases. An example of the complications in the F group is

quoted from the abstracted tibia and fibula cases—"Cases 4-9 (Four electives and two obligates—one for bone loss, one for faulty reduction). All were plate fixations. The sequestration was massive, wound healing was not achieved and the resultant scar will be excessive. These are failures in every sense and the surgery contributed directly to the prolonged disability. Bridging bone grafts will be necessary in several." The following conclusions are drawn:

1. There is a definite place for the use of delayed internal fixation in battle fractures in the fixed installations of the communications zone.

2. Its use should be as an adjunct to fracture management under the principles previously expounded for reparative surgery of compound fractures.

3. The results achieved in this group of cases are deemed very satisfactory with the exception of those in the plated fractures of the tibia and fibula and those associated with massive soft-tissue loss (obligate-4), particularly when they are evaluated in the light of their adjudged indications.

4. In the light of the results achieved in this series it seems reasonable to state that by the use of delayed internal fixation:

a. Nonunion of fractures with segmental defects or persistent distraction may be prevented in many cases, as is evidenced by the achievement of bony union in 27 (69%) of 39 cases in this series.

b. Varying degrees of malunion or, perhaps in some cases, delayed or nonunion of fractures, for which inadequate reduction was achieved by other measures, may be prevented in many cases, as is evidenced by the achievement of bony union in good apposition and alignment in 64 (85%) of 75 cases in this series.

c. Bony union in the optimal reduction of condylar fractures about the knee and elbow may be achieved, as is evidenced in 100 per cent of 15 cases in this series.

d. The obvious advantages of well stabilized maximum reduction of fractures which lend themselves to rigid stabilization and satisfactory wound healing may be achieved in many cases, provided the fixation is performed by multiple screws with minimal periosteal stripping, as is evidenced by union in good position in 94 (98%), and wound healing without sequestration or the removal of metal in 71 (74.7%) and in another 14 (14.9%) after the removal of sequestra and metal in a total of 95 cases. If plating is the method of fixation, bony union and satisfactory wound healing may be anticipated in a smaller percentage of cases, as is evidenced by union in 140 (84.3%) and wound healing without sequestration or removal of metal in 99 (50%), and readily in another 34 (20.3%) after removal of sequestra and metal in a total of 168 cases.

e. Improved apposition of the fragments may sometimes be accomplished with the aid of

wire loops, as is evidenced by the achievement of bony union in 59 (85.5%) and of wound healing without sequestration or removal of metal in 50 (72.5%), and in another 12 (17.4%) after removal of sequestra and metal in a total of 69 cases regardless of any other qualifying factors.

5. The hazard of delayed internal fixation appears to be increased sequestration, which may be explained by the periosteal stripping which the procedure entails. Sequestration occurred in 34.3 per cent of the cases in this series and it seems reasonable to state that with:

a. Screw or wire fixation, sequestration is seldom massive, does not seem to interfere with union of the fracture, and probably would have occurred in many cases had nonfixation measures been employed.

b. Plating, followed by sequestration in 41 per cent of 168 cases, is sometimes followed by massive sequestration and retardation of the attainment of full strength of the bone. It may create a massive defect reparable only by bone grafting.

6. Unless the fracture contour permits a rigid fixation by screws or unless wire loops appear advantageous, it is preferable to attempt reduction by traction or manipulation and strive for early wound healing.

a. Following wound healing, fixation by plating or other fixation is relatively nonhazardous, as is evidenced by wound healing in 95 per cent of 21 cases in this series without sequestration or removal of metal.

b. Fixations of the long bones of the upper extremity may be expected to give excellent results if the severity of bone loss or of the soft tissue injury does not prejudice the chances of union and wound healing.

c. Fixations of the femur performed on indications, with multiple screws or wire loops and with minimal periosteal stripping, may be expected to give excellent results.

d. Fixations of the tibia by multiple screws or wire loops may be expected to give very satisfactory results. Plating of the tibia should be reserved until after wound healing. In the cases of tibia fracture, 8 of the 9 failures and 6

of the 8 massive sequestrations followed plate fixation.

e. The plating of the fibula in a fracture of both bones may be a useful procedure which is relatively nonhazardous. It maintains length and alignment, aids in achieving apposition of the tibial fragments, and provides some degree of immobilization of the fracture of the tibia.

7. Internal fixation as an adjuvant to the management of the unreduced septic compound battle fracture may aid in the control of sepsis and in achieving the best obtainable result. Among 20 cases in this series bony union was achieved in good alignment in 20 (69%), wound healing without further sequestration in 13 (45.5%) and after removal of sequestra and metal in 13 (17.5%) additional.

8. The indications for delayed internal fixation can be defined only for those instances in the management of the wounded in which the advantages offered by maximum fracture reduction and (usually) stabilization would not be overshadowed by other considerations. With this qualification it may be stated that the indications for the use of delayed internal fixation in the base hospital either at the initial operation of reparative surgery or later are:

a. Obligate

(1) Segmental defects or persistent distraction of fragments

(2) Inadequate reduction by other measures

(3) Displaced condylar fractures

(4) Associated nerve surgery which can be facilitated greatly by fixation

b. Desirable (advantageous)

(1) Fractures of the long bones (especially the femur) the contour of which permits rigid stabilization by multiple screws with minimal periosteal stripping

(2) Fractures in which nonrigid fixation by wire loops will provide a degree of fracture reduction probably not attainable without it

9. Further study of this problem and a comparable study of fractures managed by nonfixation measures are definitely indicated. Each case should be evaluated in the light of the problem confronting the overseas surgeon and the anticipated result by fixation and nonfixation measures.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Rose, C. A., Hess, O. W., and Welch, G. S.: *Vascular Injuries of the Extremities in Battle Casualties*. *Ann. Surg.*, 1946, 123: 161.

This article is based on experiences in the management of 100 consecutive patients with arterial injuries of the extremities encountered in an evacuation hospital in the European campaign. Only major arteries were considered.

The diagnosis of arterial injury in the extremities was not difficult in most cases, i.e., when a cold pulseless limb was observed unilaterally. However, in two types of cases the diagnosis was less obvious. Badly shocked patients with no palpable peripheral pulses in any extremity had to be re-examined frequently for evidence of arterial injury as their condition improved. In addition, it was possible to have palpable distal pulsations in cases with small lacerations of the arteries. A firm hematoma in the region of a small wound was particularly suggestive of arterial laceration since venous bleeding rarely caused arterial compression even in such a closed space as the popliteal fossa. It was rare to find the classical signs of arterial aneurysm or arteriovenous fistula early after injury.

Plasma was used preoperatively in treating patients in whom there had been little loss of blood, but many of these patients had lost upward of 2 liters of blood and shock was frequently severe. Blood transfusions of from 500 c.c. to 3,000 c.c. were given to 55 of the 100 patients. There was practically never active bleeding at the time of admission but during treatment for shock, the rise in blood pressure was sometimes followed by recurrence of the hemorrhage. If the bleeding vessel could not be visualized and controlled quickly, a blood pressure cuff was applied as a tourniquet. Oxygen, and sulfadiazine, by mouth, and penicillin intramuscularly were all started preoperatively and continued as long as indicated.

Careful débridement was performed through the extended existing wound, but care was used to avoid damage to all vascular radicles which could provide collateral circulation. Nine patients required primary amputation because of extensive wounds more than 16 hours old which were complicated by compound fractures and severed arteries with extensive distal thrombosis. In 5 cases, arteriorrhaphy was performed. The arterial wounds were small and easily repaired in each instance, and none of the wounds were associated with extensive tissue damage. Ligation of the injured artery was done in 70 cases. Thrombosed or damaged segments were excised and the companion veins were similarly ligated and severed. Eight patients were subjected to arterial anastomosis performed by the nonsuture technique of Blakemore and Lord. One patient died at opera-

tion from a pulmonary embolism; 5 patients developed gangrene afterward; 2 operations were followed by a viable extremity. The authors believe that in both of the latter cases the collateral circulation was good enough to have saved the extremity without arterial anastomosis. Heparin was used in only 2 cases and in both of these gangrene developed. The poor results of the Blakemore method are attributed to the lack of patency of the arterial system distal to the anastomosis, even though the procedure was limited to patients treated within 14 hours of the time of injury. Eight patients were treated conservatively, i.e., by débridement only. In 2 of these, gas gangrene developed and amputation became necessary. The other 6 recovered with viable extremities. The results are given in the following table.

Treatment	Results	
	Good	Poor
Primary amputation.	0	0
Arteriorrhaphy	5	0
Ligation	33	37
Nonsuture anastomosis	2	6
Débridement only.	6	2

Postoperative treatment included the use of alcohol and papaverine for vasodilation and of sympathetic blocks with 2 per cent procaine. Refrigeration was attempted in only a few cases. Only 2 lumbar sympathectomies were done. Because of the damage to the collateral vessels which was frequently present, the effect of these various procedures was not striking. Despite the routine use of sulfadiazine and penicillin, gas gangrene developed in 12 patients, of whom 11 were subjected to amputation. Three died of the infection. There were 3 other deaths from crush syndrome, pulmonary embolism, and a severe hemolytic blood transfusion reaction, respectively.

An analysis of the results showed the factors which determined the prognosis for survival of an extremity with injury to a major artery. The time factor seemed important inasmuch as two-thirds of the limbs survived when surgery was performed within 10 hours of wounding, whereas less than one-fourth survived after 20 hours. As was expected, the prognosis was better when the degree of arterial injury was not severe. The influence of the degree of tissue damage was striking. The survival rate of the limbs with slight tissue damage was 85 per cent but only 21 per cent of those with severe tissue damage were saved. The effect of the anatomic location of the arterial wound was consistent with acknowledged principles; namely, that the prognosis for interruption of the major vessels was better in the upper extremity than in the lower extremity, and injuries that involved major collateral vessels resulted most often in gangrene.

THEODORE B. MASSELL, M.D.

Pratt, G. H.: The Surgical Management of Arterial Occlusion. *J. Am. M. Ass.*, 1946, 130: 827.

The author outlines his methods of treatment in various conditions presenting acute arterial occlusion. Traumatic laceration of an artery is repaired by a continuous fine silk stitch which does not pass through the intima. The suture line should be reinforced by wrapping a strip of fascia or muscle around the site of repair. Treatment after arterial suture includes the use of anticoagulants, sympathetic nerve blocks, and the administration of vasodilator drugs.

Incomplete laceration of a major artery may result in a false aneurysm. For arterial aneurysm the sac is obliterated but not excised, in order not to injure the collateral vessels which run in or near the sac wall. When contusion causes local thrombosis the author advocates opening of the artery and removal of the thrombus.

Embolism of a major peripheral vessel usually occurs at a point of bifurcation. While embolectomy should be done within 24 hours, the author reports success following removal of an embolus of the bifurcation of the aorta 60 hours old. An approach just below the inguinal ligament is advised. After the clots are removed the artery is washed with heparin.

Postoperative treatment includes the use of anticoagulants and sympathetic nerve blocks.

Acute occlusion may be caused by infection with the streptococcus or the gas producing group of clostridia. The presence of crepitation in the tissues does not alone constitute an indication for amputation. The diagnosis of a gas bacillus infection should be made on the clinical picture: fever, a high pulse rate, sanguineous drainage from the wound, massive edema, and the anxious sick look of the patient.

Scalenus anticus syndrome may cause thrombosis of the subclavian artery. After scalenotomy the author advises sympathetic blocks or a preganglionic thoracic sympathectomy.

THEODORE B. MASSELL, M. D.

Dandy, W. E.: Results following Bands and Ligatures on the Human Internal Carotid Artery. *Ann. Surg.*, 1946, 123: 384.

In the surgical treatment of intracranial aneurysms it is at times necessary to occlude the internal carotid artery partially as a preliminary step before totally closing the artery. A partial ligation is necessary when the Matas test indicates an inadequate collateral circulation at the circle of Willis. In a group of 6 patients in whom a band of fascia lata had been placed for this purpose and in whom total ligation became necessary later, the segment of the artery, including the band, was excised at the second operation after intervals varying between 16 and 58 days. The specimens were subjected to gross and microscopic study principally to learn what happens to the affected portions of the artery and to the band. In addition, specimens following total ligation of the internal carotid (1 case), total ligation of the com-

mon carotid (1 case), and ligation of the intracranial carotid by a silver clip (1 case) were studied.

In the 6 specimens following partial occlusion of the internal carotid artery by fascial bands, the lumen of the artery remained patent, although greatly reduced in size. In only 1 case was there any indication of a thrombus within the lumen; in this case the thrombus was a tiny nonobstructing carunclelike fibrous nodule. In all cases there was an extensive bulbous mass of fibrous tissue about the bands. The size of the swelling increased with time, and at the end of 58 days was about four or five times larger than the original volume of the fascial band. The bands showed marked fragmentation in all specimens and could be delineated only with difficulty or not at all in the older specimens. A rather surprising histological finding was the absence of any reaction throughout the intima of the arteries, there being no tendency toward vascular rupture.

In the 2 cases, following total ligation of the carotids, there was extensive thrombus formation within the lumens, and it was clear from these cases that the extent of intra-arterial thrombosis resulting from total ligation is variable and unpredictable and is not, as has been frequently stated, limited by the first sizable branch (the external carotid).

The single specimen taken 19 days following application of a silver clip to the internal carotid is included in this report because there was no thrombus on either side of the clip. This was observed on at least 4 other occasions when the site of the clip was subsequently exposed at a second operation. That a thrombus is consistently absent after the application of a silver clip cannot be stated without many more observations. However, in a series of 38 intracranial "clippings" of the internal carotid there has never been any clinical evidence of cerebral thrombosis. These findings indicate a disadvantage in the use of a clip when thrombus formation is desired to cure an aneurysm.

It is very probable, but not certain, that a thrombus always develops in time on either side of a ligation on a large arterial trunk. Doubtless this is due to injury of the intima, which must always occur. And yet, bands of fascia and aluminum, whether partially or totally occluding, appear not to do this. The development of a thrombus after ligation and its absence following application of a band, are the reasons for need of a better form of ligation of the internal carotid. When a clot forms in the carotid it may break off and send an embolus into the cerebral arteries with disastrous results; or the clot may propagate from the site of the ligation and pass directly into the cerebral vessels with the same result. Either of these eventualities is the explanation for the hemiplegias and deaths that occur from 12 to 60 hours after carotid ligations. The author is certain that they can be avoided either by means of totally occluding bands of fascia or by ligation over a band of fascia. The ligature does not then cut the intima. The latter procedure is probably preferable. and more certain.

JOHN L. LINQVIST, M.D.

Loewe, L., Rosenblatt, P., and Ilirsch, E.: Thromboembolic Disease. *J. Am. M. Ass.*, 1946, 130: 386.

The treatment of venous thromboembolic disease with the subcutaneous administration of heparin in the Pitkin menstrium was attended with lessened morbidity, prompt and rapid clinical improvement, and little or no residual edema.

After failures of treatment with other methods recovery has subsequently followed the routine administration of heparin in the Pitkin menstrium.

As a result of observations of its clinical results in 125 consecutive cases of thrombophlebitis and/or phlebothrombosis, the subcutaneous administration of heparin in the Pitkin menstrium is recommended as a safe, simple, practical, and effective method for the conservative treatment of venous thromboembolic disease.

Eleven cases are reported.

BLOOD; TRANSFUSION

Lewis, J. H., Tagnon, H. J., Davidson, C. S., and Minot, G. R.: The Relation of Certain Fractions of the Plasma Globulins to the Coagulation Defect in Hemophilia. *Blood, J. Hemat.*, 1946, 1: 166.

The authors state there is evidence that by the parenteral administration of derivatives of normal cell-free plasma in hemophilia, the coagulation defect can be modified toward normal. They present a brief history of older work on this subject, and new evidence accumulated during the past 3 years. Competent investigators have shown that the coagulation defect in hemophilic blood could not be related to deficiency in the calcium ion, prothrombin, or fibrinogen of the plasma. Consequently, the investigations were directed toward an attempt to determine where the deficiency, if any, resided. It was determined that certain globulin fractions prepared by acid precipitates of diluted cell-free plasma at pH 5.5, and also similar globulin preparations obtained by simple dialysis against distilled or tap water, contained all the antihemophilic properties of the parent plasma.

It would appear that the antihemophilic properties of these globulin preparations were not due to the removal of inhibitory materials, since the parent plasmas were active and the supernatant fluids from the globulin precipitants had no inhibitory activity and only minimal coagulation activity. Furthermore, hemophilic plasma treated by the same method did not acquire any increase in antihemophilic properties. The exact nature of the antihemophilic material is not known. It is definitely associated with the plasma globulins, but whether or not it is a lipoprotein has yet to be determined. Howell termed the material "plasma thromboplastin," but evidence is lacking as to whether or not this nomenclature is acceptable.

As part of the blood substitutes program conducted during the war, large quantities of human

plasma have been subjected to multiple fractionation by E. J. Cohn and workers in the Department of Physical Chemistry at the Harvard University Medical School, Boston. Various subfractions of the globulin group have been extensively tested for antihemophilic activity in the Thorndike Memorial Laboratory and extensive studies on the antihemophilic properties of fraction I are being carried out on adult patients in the Boston City Hospital. A discussion of these studies is presented.

Of equal importance with the shortening of the coagulation time of the circulating blood in hemophilia is the local control of hemorrhage when this occurs. The antihemophilic globulin substance acts as a local hemostatic when applied in dry form with adequate dressings to the bleeding point. Antihemophilic globulin preparations act, apparently, through the normal coagulation reaction and depend for their activity on the release of thrombin from prothrombin; hence an instantaneous arrest of hemorrhage does not occur.

Another globulin preparation may be obtained from human, bovine, rabbit, or swine plasma by a salting-out procedure. Investigators found that these pseudoglobulin preparations were thrombic in nature; they acted directly on fibrinogen without the intervention of calcium ion or prothrombin.

Hemostatic globulin is definitely superior to the antihemophilic globulin in the control of hemorrhage, since its action is immediate. In persons with hemophilia, it has been used to control bleeding following amputation, debridements, and dental extractions. In normal persons also it has been widely used, a notable example being its employment as a physiologic glue in skin grafting.

The question of possible toxic reactions to animal globulin preparation applied locally immediately arises. It may be reported that in using a rabbit hemostatic globulin, no untoward local effects or systemic reactions were observed following many multiple local applications of the substance in the control of hemorrhage in hemophilic and normal subjects.

In conclusion, the authors note that hemophilic blood appears to be deficient in some activity associated with the globulin fraction of the plasma protein. The chemical identity of the missing factor or factors is not at present known. However, it should be remembered that until final proof is obtained, both of these terms imply an association rather than identification of the antihemophilic activity with the plasma globulins.

Normal cell-free plasma and the antihemophilic globulin preparations derived therefrom will, on treatment with chloroform, give rise to a proteolytic enzyme system having some as yet undefined role in blood coagulation. In fractionations of human globulins, such spontaneous production of lytic agents has been found in subfraction II of fraction III, and occasionally in fraction I.

Hemophilic plasma does not produce such proteolytic enzyme systems in optimal amounts. Whether

this is due to the lowered amount of the precursor, or to the presence of inhibitor materials, is at present unknown.

The intravenous injection of antihemophilic globulin results in a marked acceleration of the clotting time of hemophilic blood. So far only fraction I of the plasma globulin has been used clinically. The dose of the material has not yet been determined, but single injections of 200 to 400 mgm. of the material will keep the blood of a hemophilic patient at low coagulation levels for from 8 to 12 hours.

For local hemostasis, a pseudoglobulin may be prepared from human, bovine, swine or rabbit plasma by a salting-out procedure. Thrombin from rabbit plasma has been used without untoward local or systemic reactions in amputations, debridements, and dental extractions in hemophilic patients.

HERBERT F. THURSTON, M.D.

Rainsford, S. G., and Morgan, W. T. J.: Determination of Blood Groups: Use of Rabbit Immune Serum. *Lancet*, Lond., 1946, 1: 154.

A method of rapid blood typing which would allow the accurate selection of men with group O blood for emergency transfusion was needed by the Royal Navy. It was believed that this selection would be made easier if a reagent could be supplied which would contain both anti-A and anti-B agglutinins. The difficulty of supplying such a reagent by mixing anti-A and anti-B serum from human sources was due not only to the reduction of isoagglutinin titer by simple dilution, but also to the fact that in most human sera there was some agglutininogen corresponding to that present in the cells of the blood from which the serum was obtained. The agglutinogens neutralize the homologous isoagglutinins and thus further reduce the anti-A and the anti-B titer of the reagent. These difficulties were to some extent obviated if the serum from an O blood were used; but it was found that although sera from O donors often showed higher anti-A and anti-B titers than were found in the sera of A and B bloods, they were not in most instances sufficiently potent to be suitable for use as blood grouping reagents.

Previous work by one of the authors (Morgan) on the production and properties of potent anti-A agglutinins in rabbits suggested that, if a similar serum specific for the detection of B-erythrocytes could be produced, a mixed immune rabbit serum containing these two agglutinins might be a reliable blood grouping reagent for the rapid detection of group O donors. One advantage which rabbit serum had over human serum was that at the dilution used the former was a clear colorless reagent whereas the latter was usually colored. This color rendered the rapid reading of the reactions without the aid of a microscope less definite.

Rabbits were immunized with an artificial antigenic complex made from purified human A substance. The serum was then pooled and absorbed so that the following titer was obtained for cells of different phenotype: A₁ and A₂, 20,000; A₂B,

10,000; B, 16; O, nil. To test the specificity of the rabbit anti-A serum, it was titrated in parallel with the human anti-A serum. The human serum was used at a dilution of 1:4 and the rabbit serum at a dilution of 1:200. There was complete qualitative agreement between the results obtained with the human and rabbit sera. The rapidity of the agglutinations was, however, greater with the rabbit serum than with the human anti-A serum. In the method of testing used, this greater avidity of rabbit serum for the cells was considered an important factor since the contact between the antigen and the antibody was necessarily limited because of the rapid and significant evaporation that took place from the large surface area of the mixed cell suspension and agglutinin solution.

During the early part of the investigation, and before a suitable anti-B rabbit immune serum had been produced, a mixed reagent was prepared from anti-A rabbit serum and human anti-B agglutinin. This mixed serum agglutinated all types of cells other than O within 5 minutes. The accuracy of tile agglutinations with the mixed serum was tested in a series of several thousand determinations by subsequent test tube agglutinations of the same bloods. The percentage error varied from 0.63 to 0.85 per cent. When human anti-A and human anti-B sera were used separately, the percentage error was 2.4 per cent.

For preparation of rabbit anti-B serum, the specific blood group B substance was obtained from pseudomucinous ovarian cysts. It was converted into a full antigen by combination with the conjugated protein component of the O somatic antigen of bacillus shigae by the method already described for the preparation of an artificial A antigen by Morgan. Rabbits were given serial doses of the artificial complex and were bled from 7 to 9 days after the last dose. The titer for B cells of one preparation of anti-B serum after absorption with A and O cells was 5,000; the preparation did not react against A cells at a dilution greater than 1:8. Bloods to the number of 1,093 were tested in duplicate by the tube method with the rabbit anti-B serum at a dilution of 1:25 and a human anti-B serum at a dilution of 1:4. There was complete agreement between the results obtained by the two sera, but more complete reactions were recorded with the rabbit serum. In tile agglutinations the rabbit anti-B serum was more reactive and showed greater avidity than the human anti-B agglutinin.

The accuracy of 961 rapid tile agglutinations with the mixed rabbit serum was checked by tube technique in the laboratory. The percentage of error was only 0.31 per cent. The authors conclude that the use of mixed anti-A and anti-B rabbit immune sera of high titer and avidity reduces the errors of blood grouping when O donors are to be selected rapidly from a group of untyped persons, and thus the mixed serum should prove of value in making the selection of blood for immediate transfusion more reliable.

THEODORE B. MASSELL, M.D.

Walsh, R. J.: A Report on the Transfusion of 2,386 Liters of Blood. *Med. J. Australia*, 1945, 2: 486.

The author presents an analysis of the use of 2,386 liters of blood. The reactions which occurred are discussed and the indications for transfusion are listed. Hemorrhage was the principal indication, and hematemeses was its most common manifestation.

Relatively there was a greater frequency of transfusions in obstetric practice. Two hundred and fourteen liters were used postpartum and 189 liters after abortion. Thirty eight liters were used in the treatment of ruptured ectopic gestations. Four hundred and sixty liters were used in the treatment of anemias and other blood dyscrasias. Two hundred and thirty-nine liters of blood were administered to patients suffering from carcinoma.

The author notes that the contention that group O blood is dangerous for transfusion to patients of other blood groups was not substantiated by his analysis. The alleged dangers of such a practice are examined in the light of recent knowledge and are herein discussed. Seventy-six per cent of the total amount of blood supplied was of group O. It is obvious, therefore, that group O blood was used for a large number of patients whose blood belonged to groups other than group O, inasmuch as only 49 per cent of the population have group O.

The Rh factor was found to be an infrequent cause of transfusion reactions. It is commonly stated that the most severe reactions are encountered in some of the blood dyscrasias. The data presented does not support this statement. Undoubtedly the most serious transfusion reactions are the hemolytic and the anaphylactic types. Hemolytic reactions with jaundice occurred in 4 cases. In 2, the Rh factor was found to be responsible. Two anaphylactic or anaphylactoid reactions were reported. One patient who had suffered from pernicious anemia for many years frequently neglected his treatment and reported on numerous occasions with very low red cell counts. For this reason he had received many transfusions over a period of 5 years. On this particular occasion, after the transfusion of 200 cubic centimeters of compatible blood, he suffered from an acute circulatory collapse with all the signs of an anaphylactic reaction. He gave sensitivity reactions to intradermal injections of the serum of one of the donors.

The danger of rapid transfusions to persons with a normal blood volume is stressed. Warnings for the slow administration of blood to patients with a normal blood volume have long been made by many writers, and the consequent dangers of circulatory overloading have been emphasized. There is usually little danger of circulatory overloading from the rapid administration of blood or serum to patients whose circulatory blood volume has been reduced; blood cannot be administered too slowly to patients suffering from blood dyscrasias, especially if myocardial weakness is present. Lack of consideration of this factor may be partly responsible for the impression that reactions are both frequent and serious in certain blood dyscrasias.

No evidence was obtained which would indicate that certain diseases render recipients susceptible to transfusion reactions. Sensitivity and pyrogenic reactions are discussed. The subject of pyrogens is complex. The author notes that such substances are a frequent cause of transfusion reactions, as was well shown by the experiences reported at Mount Sinai Hospital. This hospital reduced the incidence of transfusion reactions from 23 per cent to less than 13 per cent by close attention to the technique of cleansing and sterilizing apparatus. Great care to avoid pyrogens is exercised in the preparations of solutions, flasks, and other apparatus. Hospitals that pay attention to these details have a low reaction rate. The control of pyrogenic reactions rests to a large extent with the hospital or medical practitioner administering the blood.

Numerous factors cause blood transfusion reactions and are briefly mentioned. Reactions due to impurities in the solutions are minimized by the use of good quality chemicals. Clot formation in collected blood will render it toxic, just as defibrinated blood was found too toxic for general use. Small clots in a flask of blood are difficult to detect, but they are often responsible for reactions. The use of a blood filter will not remove their noxious influence. Hematoma formation due to difficulty in venepuncture either in the donor or in the recipient may be responsible for pyrexial reactions. Finally, undue venous congestion in the arm or leg of the recipient, caused by prolonged application of a tourniquet, may result in venous stagnation, with adverse effects on the recipient. In normal persons venous tourniquets may cause fainting and nausea if applied for too long a period.

HERRERT F. THURSTON, M.D.

Grossman, C. M., and Seward, E. W.: Homologous Serum Jaundice following the Administration of Commercial Pooled Plasma. *N. England J. M.*, 1946, 234: 181.

The authors report 8 cases of hepatitis with jaundice following the use of commercial pooled plasma, one of which proved fatal.

These patients had incubation periods ranging from 54 to 139 days, which is in conformity with the incubation period of the experimentally induced disease. Only one of the patients was seriously ill. The autopsy findings in this case differed in no way from those in cases ending in death following hepatitis due to the administration of yellow fever vaccine, nor are the findings different from those in deaths from infectious hepatitis.

In the two-year period during which these cases were observed, 501 transfusions of commercial pooled plasma were administered. The plasma was purchased from a commercial manufacturer with nationwide distribution facilities, who states that each pool consists of at least 50 samples. The occurrence of 8 cases of hepatitis with jaundice gives an incidence of 2 per cent, but this represents a minimal rather than a true incidence, since many patients received more than one transfusion of plasma, and

patients who developed hepatitis and were treated as outpatients, or by physicians elsewhere, did not come to the authors' attention. Furthermore, patients who did not develop clinical jaundice but nevertheless had the clinical features of acute hepatitis, such as nausea, vomiting, anorexia, and malaise, were not included.

The true incidence of this condition is not known at the present time. Reports in the literature vary from as many as 26 of 47 cases receiving pooled serum to 10,000 transfusions of pooled plasma without any recorded evidence of homologous serum jaundice, although in the latter report the authors state that their method may not have supplied complete data. The reasons for this discrepancy are manifold.

Since there is a relatively high incidence of infectious hepatitis at the present time, it is only natural to attribute any example of this clinical picture to spontaneously occurring agents. The long incubation period of homologous serum jaundice separates the disease from the etiological event by such a long period that causal relation may be overlooked. Finally, many physicians may not be alert to this possibility because of the absence of

information about this condition in the literature until the last few years. The incidence of this disease is undoubtedly becoming greater because of the increased use of commercially pooled plasma in cases in which transfusion of whole blood from a single donor was formerly used. The authors' experience confirmed this, since nearly 1,000 whole blood transfusions were given in the same two-year period with no case of manifest jaundice. The chance of the etiological agent's being given in any blood plasma therapy is many times increased as pools of 50 or more donors are mixed. The amount of icterogenic plasma necessary to contaminate a pool is minimal, since the disease can be transmitted by as little as 0.1 cubic centimeter.

In view of the disability, and the chance of fatality in homologous serum jaundice, the use of pooled plasma is not without danger. The fact that the icterogenic agent is not destroyed by drying and prolonged storage makes the tracing of the icterogenic sample difficult. Since it has been reported that the agent is destroyed by ultraviolet radiation, perhaps the hazard from the use of pooled plasma could be obviated by such a method.

CHARLES BAXON, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

Lam, C. R., and Hooker, D. H.: Pulmonary Embolism. *Ann. Surg.*, 1946, 123: 221.

The present review on pulmonary embolism is based on 118,611 operations performed during a twenty-one year period (1924-1944) at the Henry Ford Hospital, Detroit, Michigan. Of 280 cases of pulmonary emboli, 78 were fatal, an incidence of 1 fatality in every 1,500 patients operated upon. In 70 per cent of the fatal cases, the diagnosis was established at autopsy.

The authors point out that in the year of 1930, before the days of heparin, dicumarol, femoral vein ligation, and early ambulation, there was not a single case of fatal pulmonary embolus, while in 1943, when all of these preventive measures were available, there were 8 fatalities, although none of the 8 patients was given any specific prophylactic treatment.

All cases, fatal and nonfatal, are tabulated as to sex, age, type of surgery, and day of occurrence. Pulmonary embolism was more common in men than in women, the ratio being 3 to 2. Age increases the incidence of this complication, especially in the fifth decade, and fatalities occurred most often in the sixties.

The complication occurred most frequently following abdominal procedures. Gastric operations and prostatectomies were the worst offenders and showed an incidence of about 1 in 100 for fatalities; cholecystectomy showed an incidence of 1 in 500; hysterectomy, 1 in 600; hernia and appendectomy, 1 in 1,300.

Two peaks of fatal embolism were noted; namely, the sixth and eleventh days. This would correspond to the time of getting the patients up to go home at the end of 1 or 2 weeks, respectively. The authors believe that early ambulation may change this figure.

The clinical symptoms and signs are chest pain, more common in the right side—the ratio of pain on the right side to that on the left being 5 to 3. Hemoptysis, physical findings, and roentgenographic signs were each present in about half the cases. A friction rub was present in a third of the cases, and an effusion was demonstrated roentgenologically or by thoracentesis in a fifth of the cases.

One-half of the patients died in 10 minutes; three-fourths died in less than one-half hour, and 10 per cent of the patients lived for more than an hour, so that theoretically it would have been possible to operate upon a fourth of the patients, provided the circumstances were ideal.

The use of heparin and dicumarol is considered. Should these substances be given as a preventive to such large numbers of patients and, if so, what about the hemorrhagic complications? The authors believe that watching for local signs of thrombosis in the

legs, and the early performance of femoral vein ligation may be of value. Vein ligation was carried out in many of their cases, but these cases were not included in the present series because they had no emboli. The authors believe that early ambulation offers the most promise as a preventive measure.

BYFORD F. HESKETT, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Slaughter, W. B., and Wong, W.: The Early Management of Facial Injuries. *Surg. Clin. N. America*, 1946, 26: 2.

Since the early care of facial injuries is of great importance cosmetically, functionally, and psychologically, the excuse that other body injuries prevent adequate care is not excusable. With good clinical judgment, much can be done without endangering the patient's general condition.

Once clinical evaluation of the total body injury has been made, treatment instituted as indicated, and the immediate emergency is over, the facial injuries should be considered. A thorough physical examination of the face should be made. For ease and completeness a set routine should be followed.

The soft tissue injuries are usually readily apparent but should be noted carefully. It should be remembered that the swelling of these tissues may readily obscure the underlying bone defects.

Examination of the bony structures is best done bimanually, with gentle comparison of the two sides of the face. First the frontal area is examined, then the supraorbital ridges and the zygoma. The eyeball should be observed closely and an ophthalmologist called if necessary. The nasal bones are palpated for symmetry and to elicit motion or crepitus. The close association of the nasal bones with the maxillae, the frontal, lacrimal, and ethmoid bones, and the frequency of extensive associated fractures should be borne in mind. The nose should be examined intranasally for displacement of the cartilaginous portions. Examination of the maxillae should include palpation of the alveolar ridge and study of the occlusion of the teeth. Displacement of the orbital contents should be looked for. The mandible is examined in much the same way. X-ray studies are then made to confirm and localize whatever changes have been found.

Treatment may be immediate, delayed, or late in facial injuries. The immediate, which includes management of shock, control of hemorrhage, relief of pain, and splinting of parts, is the service which offers the patient maximum benefit, and the best possible treatment is therefore mandatory.

Primary suture is desirable and may be done within 4 hours in dirty wounds, and 6 hours in clean wounds. However, the adequate use of sulfonamides

and penicillin may make it possible to shade these arbitrary figures so much that wounds of several days' duration in the soft tissues may be closed primarily. The abundant supply of blood and the local tissue immunity of the face make for better wound healing than in other parts of the body.

Wounds are cleansed by the gentle use of a mild, nonirritating soap and frequent irrigations with normal salt solution or sterile water. At least from 5 to 8 minutes should be used for scrubbing away the debris and loose tissues in the wound. Until proper cleansing can be done, clean or sterile dressings are placed over the wound. Usually ordinary sedation is sufficient, but a general anesthetic should be used if necessary.

Abrasions are the most common facial injury. Dirt and debris ground into the wound must be removed. An oil solvent may be used and a pointed instrument may be resorted to, to remove individual particles.

Lacerations about the face need special care because a cosmetic as well as functional result must be obtained. A stellate laceration, common over the forehead, is best treated by excision of the fragmented edges undermining the wound and suture in a single line. Attention should be given to the lines of Langer. To minimize scar formation all tension must be removed from the skin edges. Adequate undermining and interrupted buried tension sutures are used. The author describes special sutures used to achieve these results. Skin sutures are removed in from 24 to 48 hours, and a firm dressing is applied to aid in splinting the wound. Lid lacerations should be repaired with great care to prevent notching, cicatricial ectropion, and subsequent damage to the eyeball. The conjunctiva and the skin are sutured separately. The tarsus should be brought together accurately. Lacerations about the nose must be repaired with careful attention to symmetry. Lacerations about the tip of the nose should not be sutured heavily as the blood supply is easily interrupted. Lacerations of the lip call for hurried tension sutures and accurate matching of the mucocutaneous line of each side. Lacerations of the tongue heal readily, and a minimum number of interrupted silk sutures are used for approximation. Ear lacerations are usually difficult to repair. The cartilage must be in accurate apposition so a terraced effect does not result. It is usually not wise to trim fragmented or semimacerated skin for fear of the resulting insufficiency of skin to cover the cartilage. The skin is carefully sutured and then a mold of the posterior surface is formed and pressure applied to prevent a hematoma. The danger of ischemia should be remembered. Local anesthesia with infiltrated novocain may be used although early suture can sometimes be done without anesthesia.

Fractures of the facial bones should be treated after more serious injuries have been taken care of. While the earlier these fractures are treated the less likely complications are apt to occur, 48 or more hours may ensue. The co-operation of neurosurgeons,

orthorhinologists, and oral surgeons may be advisable in severe fractures.

Depressed fractures of the frontal bone with involvement of the inner table and symptoms of compression call for a neurosurgeon. Replacement of depressed fragments of the outer table only can be done if not too difficult, otherwise the wound may be allowed to heal and the defect filled later with autografts of bone or cartilage.

Marked disfiguring facial asymmetry results from depressed fractures of the zygomatic bone. Usually elevation, by one of several methods, of the depressed fragment is sufficient, although in some cases open reduction and fixation of the zygoma to the frontal bone with wire will be necessary.

Depression and lateral displacement is the usual accompaniment of fracture of the nasal bones. With cocaine anesthesia given intranasally and novocaine subcutaneously over the bridge, elevation of the depressed fragment and manipulation to proper alignment can be done. Intranasal and extranasal splinting is done, the intranasal splint being removed between 48 and 72 hours; the extranasal splint may be left on for a week. In severely compounded depressed fractures, for which externally molded splints are not feasible, an attachment to a headcap appliance may be necessary to hold the depressed fragment in position. If such treatment is unavailable or the result unsatisfactory, a rhinoplastic procedure may be done later.

Maxillary fractures vary greatly in extent and severity. Mechanical ingenuity is greatly needed in contriving fixation. Each case must be studied on its merits and if the mechanics of the fracture are understood, the treatment will be evident. Packing of the maxillary sinus for several days may be necessary to hold comminuted depressed fragments in position. If severely impacted fractures are not readily loosened, traction over properly constructed arch bars must be done. After reduction, fixation can be accomplished by wiring of the teeth of the maxilla to the normal mandible, proper occlusion being the guide to satisfactory reduction. In downward displacement of the maxilla, the *Federspiel* or any similar method may be used with a plaster headcap and traction exerted in the direction necessary for the best correction. This is followed by maintenance of the reduction by external fixation.

Mandibular fractures are the most common of facial fractures. Because of the anatomic structure, fracture from force may occur on the opposite side as well as at the site of application of the force. Common sites in order of frequency are: (1) region of the angle; (2) the mental foramen, (3) the molar of the angle; (4) the symphysis, (5) the condyle, and (6) the coronoid region. Reduction of the fracture and the coronoid region, while not hindering maintenance of normal occlusion, is done by lingual swallowing or obstructing breathing, or wiring of the teeth, external skeletal fixation, or especially made dental splints. Since these fractures are almost always compounded through a tooth socket or into the mouth itself, early fixation to

avoid infection is imperative. Abscesses should be drained extraorally when indicated.

Alveolar process fractures occur in children and young adults. Any fragment with attachment to soft tissue should be saved. Fixation to adjacent teeth is necessary for stabilization.

After functional results are obtained, plastic procedures for cosmetic and psychological considerations may be considered. Lengthy operative procedures offering but slight improvement in the end should be avoided. In such cases, facial prosthetics should be considered. Wide disfiguring scars may be excised and replaced by a hairline scar if principles mentioned earlier in suturing are adhered to. Contracting scars causing ectropion of the eyelids and lips, and distortion of the nares may be corrected by the Z-plastic procedure. Full thickness grafts, pedicled grafts, cartilage, or bone may be considered in the late cosmetic correction of facial deformity.

EARL H. KLABUNDE, M.D.

Genes, S. G., Dinerstein, Z. M., Schelnerman, M. D., Baf, M. I., and Others: The Treatment of Wounds with Acidophil Paste and Acidophil Serum. *Vrachebnoe Delo*, 1945, p. 59.

The authors used acidophil serum and paste in the treatment of 27 patients with poorly granulating wounds caused by missiles or shrapnels, 10 with osteomyelitis, 34 with frostbites, and 1 patient with a burn. As a rule, the paste was applied daily. The treatment was supplemented by the administration of from 100 to 120 mgm. of ascorbic acid. Only such wounds with poor granulations were treated which did not show any improvement after the customary therapy with naphthalan, chloramine, potassium permanganate solution, cod liver oil, hypertonic saline solution, brilliant green, methylene blue, quartz lamp irradiation, blood transfusions, and skin transplantations. After the first 3 days of treatment with acidophil paste the necrotic tissue began to disappear and the number of pathogenic microorganisms, such as the streptococcus, staphylococcus and bacillus pyocyaneus, began to diminish. The odor subsided and gradually the granulation tissue became brighter. In the majority of cases the wounds healed in from 1 to 3 months although previous treatment with other methods continued for 12 or 15 months had failed. Failure was recorded in only 3 of 27 patients.

The results were less spectacular in frostbites if the treatment was instituted more than 6 months after necrotomy. However, if the treatment was instituted a few days after the necrotomy, extensive wounds healed in 1 or 2 months.

Osteomyelitis was treated with acidophil serum injected daily through the fistulous ducts. Considerable improvement or complete cure followed.

The treatment failed in 1 case of a burn, 5 cases of osteomyelitis, and 2 cases of slowly granulating wounds.

The burning sensation after the application of the paste usually disappears after the first 3 or 4 days of

treatment. Occasionally, small ulcers appear in the scar tissue, but they heal promptly. Sometimes the introduction of acidophil serum into a fistula is followed by a chill, rise in temperature, and malaise, but the symptoms disappear after 1 or 2 days. The beneficial effect of the treatment is attributed by the authors to the creation of an acid medium which interferes with the multiplication of the majority of the pathogenic microorganisms. Furthermore, lactic acid causes a vasodilatation in the wound, with a resulting hyperemia and intensification of the phagocytic properties of the leucocytes. The presence of casein in the paste contributes to the desiccation of the wound, and the presence of fat prevents adhesion of the gauze to the tissues and softens the scar. Finally, there is the possibility of a local effect of vitamins A, D, and C on the wound.

The paste and the serum are prepared from lactic acid.

JOSEPH K. NARAT, M.D.

Palladin, A. V.: The Synthetic Production of Vitamin K and Its Use in Hemorrhages and the Treatment of Wounds. *Vrachebnoe Delo*, 1945, p. 9.

Vitamin K formed by plants, vitamin K₁ formed by bacteria, and synthetic vitamin K₂ (methyl-naphthoquinone) are usually employed in the presence of hypoprothrombinemia, e.g., for hemorrhages accompanying septicemia, peptic ulcer, and typhoid fever, and also for the hemorrhagic diathesis of infants.

Biochemical research by the author convinced him that synthetic vitamin K products are able to stop parenchymatous hemorrhages resulting from war injuries, surgical operations, or pathological conditions accompanied by vascular disturbances. Such synthetic products are effective no matter whether the amount of prothrombin in the blood is normal or diminished. The author studied 2 synthetic products, namely, methyl-naphthoquinone, or vitamin K₂, and a water soluble product which he developed and called "vicasol." The first mentioned product is a yellow greenish powder, poorly soluble in water but easily soluble in 96 per cent alcohol and oil. From 10 to 15 mgm. of the product were given to the patient orally in the form of an alcoholic solution. This daily dose was repeated for 3 to 5 days in succession. The formula of vicasol is $C_{11}H_8O_2SN$, and the product appears in the form of a white crystalline powder soluble in water. It has a bitter taste, does not irritate mucous membranes, is stable, and is not decomposed by light. Vicasol was given orally in the form of tablets containing 15 mgm. of the active substance. One tablet was given daily for 4 or 5 days in succession.

Both products eliminate hypoprothrombinemia and cause a restitution of the normal blood clotting. Moreover, both products are able to stop hemorrhages from granulating wounds and lung injuries. The products proved effective also in stopping hemorrhages after tonsillectomies, arthrotonies, and stomatological operations.

INTERNATIONAL ABSTRACTS OF SURGERY

Prophylactic administration of either product for 2 or 3 days before the operation diminishes the danger of hemorrhage after tonsillectomy. Good results were observed also after the administration of either product following surgical procedures necessitated by osteomyelitis of the upper jaw, and following war injuries. Hemorrhage during and after the operation was considerably diminished following the prophylactic use of the drugs, which also obviated the necessity of placing sponges in the maxillary sinus for the purpose of hemostasis.

The drugs are rendering good service after tooth extractions.

Both products proved efficient in stopping hemorrhages from hemorrhoids or the nose. Also, bleeding caused by pulmonary tuberculosis could be controlled by either product. Similar results were obtained in the treatment of parenchymatous gynecologic hemorrhage following endometritis, inflammatory processes in the adnexa, and also juvenile and preclimatic hemorrhages. Bleeding attributable to scurvy could be promptly stopped by either product. The healing process in superficial wounds could be accelerated by vicasol or methyl naphthoquinone.

The author's observation led him to the conclusion that the original theory concerning the mechanism of the physiologic action of vitamin K is incorrect because the vitamin or its substitutes are effective also in conditions not accompanied by hypoprothrombinemia.

JOSEPH K. NARAT, M.D.

Wells, D. B., Root, M. T., Kendall, R. E., and Leonard, J. C.: A Symposium on Burns from the Hartford Circus Disaster. *Occup. M.*, 1946, 1: 99.

The reports presented in this symposium teach a number of significant lessons in the treatment of burns.

The Hartford circus disaster, which involved the life and health of a considerable number of people, demonstrated the importance of constant preparedness for such civilian catastrophes. In large part, the favorable results obtained in the management of this group of burned patients came from wise prearranged specific organization of the community and that in hospitals. The adequate staff, aides, facilities, and supplies readily available paid large dividends and made possible the prompt exhibition of modern methods.

A Burn Committee had previously developed a plan of action for the Hartford Hospital. This committee sprung into action at the time of the fire and its recommended procedures were applied almost immediately. Remarkably favorable physical and emotional responses resulted from the mass method of handling this group of seriously ill and psychically traumatized people.

From the point of view of the laboratory in the management of burns, estimations of the hemocoagulation, for the purpose of determining the

degree of shock, are essential for early function. The authors improvised a setup for securing the specific gravities by the copper sulfate falling drop technique; this was found to be of assistance in directing the use of plasma, transfusion of whole blood, and nutritional therapy.

In the author's experience, this method offered a simple, rapid, and reliable guide to the hemocoagulation in burn shock. DAVID H. LYNN, M.D.

Walker, J. Jr., Saltonstall, H., Rhoads, J. E., and Lee, W. E.: Toxemia Syndrome after Burns. *Biochemical and Pathological Observations and Studies. Arch. Surg.*, 1946, 51: 177.

Patients who have sustained severe extensive burns exhibit two reactions to their injuries—shock and toxemia. At one time it was thought that the two were one process, but it is possible to distinguish between them. Shock, occurring very shortly after the burn has been sustained, and ending usually within the first 24 hours, is marked by hemocoagulation, hypotension, tachycardia, and cold extremities; on the other hand, toxemia, appearing on the second day and usually lasting 3 or 4 days, is marked by headache, vomiting, fever, oliguria, disorientation, myoclonus, and some evidence of renal and hepatic dysfunction.

Severely burned patients admitted to the Pennsylvania Hospital, and to other Philadelphia hospitals, have been studied for signs of burn toxemia. The quantitative van den Bergh test demonstrated some hepatic damage, which was much more marked when tannic acid or some other tanning agent was applied to the burned areas than when petrolatum and pressure dressings were used. However, avoidance of tanning agents seemed to have little effect on the mortality in burn cases. Renal damage was estimated by studies of the urine and elevation of the plasma nonprotein nitrogen. All patients had some elevation. Of the 20 patients who had a level of over 100 mgm. per hundred cubic centimeters of plasma, 9 died. An "undetermined" nitrogen, the residue unaccounted for after determination of the urea, uric acid, creatinine, and alpha amino nitrogen fractions, was found to represent from 60 to 80 per cent of the rise in nonprotein nitrogen in the toxemic patient and served as a useful index of the presence and severity of toxemia during the first week after the burn.

Pathological studies were made of the organs of patients who died in from 2 to 6 days after the burn, in what was clinically burn toxemia. The livers showed fatty infiltration but no actual necrosis. The kidneys showed rather pronounced toxic nephrosis with degeneration of entire tubules. In the adrenals there was no gross hemorrhage, but the inner zone of the cortex showed edema and degeneration. Gross examination of the brains showed edema and some herniation of the cerebellar tonsils through the foramen magnum with consequent compression of the medulla oblongata. Microscopic sections showed general toxic degeneration of ganglion cells,

most evident in the cortex and the hypothalamus. In general, the bodies of these patients were edematous and flabby, and the edema seemed unrelated to the amount of fluid administered therapeutically to the patient. The tissues having a high consumption of oxygen seemed to have sustained the greatest damage.

In conclusion, the authors stress the importance of the disproportionate rise in "undetermined" nitrogen, which cannot be entirely explained on the basis of renal damage. Although some deaths from burns are the result of overwhelming kidney damage, still others appear to result from damage to the central nervous system. The process of burn toxemia is a widespread one, for which no specific treatment is yet known. **B. F. LOENSBURY, M.D.**

Gerber, I. E., Schwartzman, G., and Bachr, G.: The Penetration of Penicillin Into Foci of Infection. *J. Am. M. Ass.*, 1946, 130: 761.

Intermittent intramuscular injections of large doses of penicillin at 3 hour intervals seem in general to be more effective in the control of bacteremia and of local infections than continuous intravenous administration of the same total daily amount.

The intramuscular administration of penicillin in divided doses has the distinct advantage of producing a higher peak level in the blood intermittently throughout the day, and thereby favors the penetration of penicillin into vegetations of acute and subacute bacterial endocarditis and into suppurative thrombophlebitis or other primary sites of bacteremia.

To assure the penetration of adequate amounts of penicillin into primary foci responsible for bacteremia (i.e., vegetations, thrombophlebitis), additional massive "booster doses" several times a day are often desirable. Such "booster doses" should be five or six times the routine intramuscular dosage which has produced blood levels sufficient to clear the blood of bacteria.

Subacute bacterial endocarditis and other chronic infections due to organisms of relatively high penicillin resistance are more advantageously treated with massive doses at frequent intervals throughout the day (every 3 hours). The minimum duration of therapy should be 5 weeks.

In purely localized infections with highly resistant organisms, such as actinomycetes, penicillin is best concentrated in a few massive intramuscular doses each day in order to favor penetration by means of exceptionally high peak levels, and, if possible, also administered directly into the infected area.

CHARLES BARON, M.D.

Trumper, M., and Thompson, G. J.: Chilling Penicillin. *J. Am. Med. Ass.*, 1946, 130: 627.

The present study was undertaken with a view to finding some method of obviating the need for the injection of penicillin every few hours. The authors state that effective blood levels can be obtained by chilling the site of the injection.

Patients with gonorrhea were studied. An ice bag of 80 ounce capacity, filled with crushed ice, was placed about the upper shoulder, fastened by a supporting harness, for a period of 2 hours, following which chilled penicillin (100,000 units in a 10 c.c. solution) was slowly injected into the deltoid muscle. The ice bag was then replaced for a period of 12 hours, refilling it as necessary. Cure of the gonorrhea and negative smears were obtained with the use of this method in 91 per cent of the cases. However, with higher doses, i.e., 150,000 units of penicillin, a 95 per cent cure should be expected.

The method used compares favorably with results reported following the use of multiple injections, or single injections of penicillin in beeswax and peanut oil.

The chilling method not only reduced, to one, the number of injections required for treatment of uncomplicated gonorrhea, but also rendered the injection painless, and made the injection of any other foreign substance unnecessary.

ARTHUR J. LESSER, M.D.

Hamilton, J. E., Prandoni, A. G., Evans, J. M., and Romansky, M. J.: Penicillin Therapy of Infections in 220 Patients. *Surgery*, 1946, 19: 186.

The Penicillin Committee at Walter Reed General Hospital, Washington, D. C., reports the use of the drug in 255 conditions in 220 patients from July, 1943 to September, 1944. Attention was directed toward large dosage rather than minimal dosage, varying from 90,000 units a day in the susceptible gonococcal, streptococcal, and pneumococcal infections, to 500,000 units a day in the more resistant staphylococcal, anaerobic clostridial, and actinomycetic infections.

Complications due to the penicillin therapy were minimal, urticaria being the most common. In no instance of 13 cases of carbuncle and furuncle was it necessary to incise and drain the infection. Among 20 cases of cellulitis and abscess of the soft tissue in general, 5 responded to penicillin which did not respond to sulfonamides. The drug was used in extensive clean or in contaminated operative cases as an adjunct to surgical procedures and was found to be of indisputable value. In skin grafting and primary closure of pilonidal sinus excision wounds its value is still to be proved.

Sequestration was prevented in 4 cases of acute osteomyelitis and an increased dosage of penicillin was suggested in all early cases. One case of penicillin cure in a patient with a brain abscess secondary to lung abscess was unique. In empyema the drug was found useful in controlling early systemic infection or accompanying pneumonia, but if pus continued to form from the tenth to the fourteenth day after penicillin had been given intramuscularly and intrapleurally, rib resection was advised and performed.

In lung abscess without lobectomy, it is the author's opinion that penicillin is vastly superior to the sulfonamides and in the great majority of the

cases the early abscess will yield to the drug. Four cases of lobectomy for lung abscess were reported. All of the patients developed a postoperative putrid empyema but all recovered.

The drug was used in a variety of medical diseases. In the actinomycetic infections there would appear to be a wide variability in susceptibility to the drug. Appraisal of its efficacy in brucellosis is withheld.

E. A. GORVETT, M.D.

Barber, M., Nellen, M., and Zoob, M.: Erysipeloid of Rosenbach: Response to Penicillin. *Lancet*, Lond., 1946, 1: 125.

Human infection with erysipelothe *rhusiopathiae*, the organism of swine erysipelas, is sufficiently uncommon for any proved case to be worth recording. Recently, 7 patients with clinically diagnosed erysipelothe of Rosenbach were admitted to the hospital, and in 5 of them the diagnosis has been bacteriologically confirmed. These cases are believed to be the first in humans to be treated with penicillin, although Heilman and Herrell (1944) have successfully treated experimental erysipelothe infection in mice with penicillin.

Of the 5 cases of bacteriologically confirmed erysipelothe of Rosenbach reported, 3 were treated with penicillin intramuscularly, which appeared to effect a complete recovery in 48 hours. These 5 cases and 2 other clinically similar ones were all admitted within a period of 4 months.

BENJAMIN GOLDMAN, M.D.

North, E. A., and Christie, R.: Acquired Resistance of Staphylococci to the Action of Penicillin. *Med. J. Australia*, 1946, 1: 176.

After testing more than 100 strains of staphylococci, Spink, Hall, and Ferris, in 1945, failed to find a single strain not previously exposed to penicillin that was not inhibited by 1 unit of penicillin per cubic centimeter. The authors, also, believe that naturally occurring penicillin-resistant staphylococci are rare. However, a large number of strains isolated from patients receiving penicillin show considerable resistance to this drug by the standard sensitivity tests. Up to this time there was no evidence to indicate whether the resistant strains were descendants of sensitive organisms already in the wound, or contaminants with naturally resistant strains or strains which had acquired resistance and become disseminated through the wards.

The authors have isolated some penicillin-resistant staphylococci which are without doubt variants of sensitive parent organisms which acquired resistance to penicillin in vivo.

When the parent penicillin-sensitive strain of staphylococci was compared with the penicillin-resistant strain, which had developed in vivo, by the mouse pathogenicity test, it was found that their killing power was identical within the limits of experimental error.

Next, the ability of penicillin to prevent death in mice was investigated. It was found that penicillin

saved the mice infected with a penicillin-sensitive strain, while similar treatment failed to save the mice infected with penicillin-resistant staphylococci. This experiment is of more value because the resistant organism is almost certainly a direct descendant of the sensitive strain. This is assumed because of the rarity of the strain, and the similarity between the coagulase formation, fibrinolysis, hemolysis, pigment formation, and serological typing of the strains.

The penicillin-resistant strain developed in vitro differed considerably from the parent strain in biological and metabolic characteristics. However, numerous subcultures on nutrient broth caused this strain to resume the characteristics of the parent strain, including its sensitivity to penicillin. When the killing doses of these organisms were investigated, the penicillin-resistant strain developed in vitro was almost completely avirulent while its parent strain killed mice to the same extent as the strains investigated in the first part of the experiment.

When a rabbit was injected with a penicillin-resistant strain developed in vitro it suffered no ill effects. The organism was recovered once from the blood stream and still found to be resistant to the same amount of penicillin. When the parent strain was injected, the rabbit died.

The authors in 2 different experiments confirmed the findings of Spink, Hall, and Ferris (1945)—that a penicillin inhibitor can be extracted from staphylococci that have acquired resistance in vivo, but not from resistant variants developed in vitro.

The results of these experiments seem to support the theory that resistance to penicillin developed in vitro is only temporary, while resistance acquired in vivo as a result of penicillin therapy is more permanent. These organisms also seem to retain their full pathogenicity.

So far there is little evidence to support the idea that these resistant strains developed in vivo have been a major cause of the failure of penicillin therapy. The authors subcultured for 30 days 6 resistant strains obtained from infected wounds without altering their resistance to penicillin, their invasiveness, and their pathogenicity. One strain was passed through animals three times and its resistance to penicillin was unchanged. The authors' work confirmed the findings of Warner and Amlund: the effect that certain penicillin-resistant strains were as resistant to concentrations of penicillin in vivo as to those in vitro.

In the light of recent evidence in the literature and the authors' experience, it is likely that penicillin-resistant staphylococci may become a clinical problem in the future.

ROBERT R. BIGLOW, M.D.

Foshay, L., and Pasternack, A. B.: Streptomycin for Tularemia. *J. Am. M. Ass.*, 1946, 130: 393

It is noteworthy that each of the first 6 patients given streptomycin for tularemia experienced relief from the distressing general symptoms of headache, mental dullness, the sense of prostration, arthralgia,

myalgia, chills or chilly sensations, and nausea before the end of the first day of therapy. This effect was a striking feature by the end of the second day, and it appeared even with very low, possibly suboptimal, dosage. The authors infer that bacteriostasis, which must undoubtedly have occurred within the first 12 hours of therapy, is associated with failure of the bacteria to elaborate the diffusible substances that lead to the production of these symptoms. Failure of papular primary lesions to ulcerate, even after incision, seems also a result of bacteriostasis or a regional bactericidal effect.

It is probable that the authors gave too little streptomycin, or gave it for too short a period, to obtain the best possible results in several cases.

Administration by continuous subcutaneous drip, which seems to be tolerated better than continuous intravenous drip, would have been more effective than intermittent intramuscular administration in securing high initial blood and tissue concentrations, the most important factors for successful therapy with all bacteriostatic and bactericidal agents.

The authors were unable to determine streptomycin concentrations in the blood or serum at the time these patients were treated. From later studies they infer that the administration of 30,000 units every 3 hours maintained concentrations between 2 and 4 units per cubic centimeter of serum during the period of administration.

Comparison with serum therapy. Comparative estimates of the effects of these therapeutic agents were unavoidable. With due regard for the small size of the streptomycin series, one feature was outstanding: the uniformity of the clinical responses in character, degree, continuity, and time of appearance. Although the authors have records of serum treated patients that compare favorably with the cases recorded here, these cases could not be matched by any 7 case records of the serum treated patients selected at random.

The responses to serum therapy have always shown a wide range of variability in character, degree, continuity of effect, and time of appearance. This has been attributed chiefly to variability in the efficiency of individual defense mechanisms as they were aided by a bacteriostatic agent. The administration of a bactericidal agent that acts directly on bacteria and independently of the variable, individual defense mechanism possibly accounts for the observed uniformity of the responses to streptomycin.

JOHN J. MALONEY, M.D.

Miller, C. P., and Bohnhoff, M.: Streptomycin Resistant Cocci. *J. Am. Med. Ass.*, 1946, 130: 485.

Drug resistance or "fastness," that is, the acquisition by micro-organisms of tolerance for chemotherapeutic agents, has long engaged the attention of bacteriologists and parasitologists and has recently become a matter of concern among clinicians and epidemiologists. Resistant strains of micro-organisms usually susceptible to the sulfonamides have been recognized for some time, and penicillin resist-

ant strains are now beginning to appear in the clinic and laboratory. The apprehension which might have been caused by the latter is currently being allayed by the introduction of streptomycin.

It should be pointed out that the observations have been made on micro-organisms which have been rendered drug resistant by artificial means, and that these findings must not be assumed to apply by analogy to naturally resistant strains if and when they arise. The relation of artificially acquired and naturally acquired resistance to chemotherapeutic agents involves many questions as yet unanswered.

Repeated cultivation of gonococci and meningococci on mediums containing increasing concentrations of streptomycin enhanced their streptomycin resistance rapidly—within 4 to 6 transfers—to such a degree that growth occurred on concentrations of 75,000 units per cubic centimeter, the highest concentration employed. These streptomycin resistant meningococci remained fully virulent for mice and produced lethal infections with generalized sepsis in spite of treatment with 15,000 units of streptomycin, the maximum dosage tolerated by the animals. Similar infections with the same strains before they had become resistant were regularly cured by doses of from 70 to 100 units of streptomycin.

Streptomycin resistant meningococci were susceptible in vitro and in vivo to penicillin, and penicillin resistant meningococci were susceptible to streptomycin in vitro and in vivo.

Gonococci resistant to either drug were susceptible to the other in vitro.

Streptomycin resistant micro-organisms did not show the gross and microscopic abnormalities observed in penicillin resistant strains.

It is concluded that the mode of action of streptomycin on these micro-organisms differs from that of penicillin.

JOHN E. KIRKPATRICK, M.D.

Weinstein, L.: Typhoid Bacillus Infection of a Surgical Wound; Treatment with a Urethane-Sulfanilamide Mixture. *N. England. J. Med.*, 1946, 234: 184.

In spite of the fact that a moderate number of patients with typhoid fever develop complications requiring operative intervention, such as incision and drainage for osteomyelitis or laparotomy for intestinal hemorrhage or perforation, and that the *Clostridium typhosum* is capable of producing localized areas of infection, there is a scarcity of reports concerning suppurative complications of surgical wounds.

The author reports a case of typhoid bacillus infection in a surgical wound of the leg, without underlying osteomyelitis or periostitis, in a patient who probably had an undetected mild attack of typhoid fever several weeks prior to operation for the open reduction of a fracture of the femur. Had the patient not incurred a fracture of the hip, with subsequent infection of the operative wound by the typhoid bacillus, the diagnosis of typhoid fever would in all probability never have been made.

cases the early abscess will yield to the drug. Four cases of lobectomy for lung abscess were reported. All of the patients developed a postoperative putrid empyema but all recovered.

The drug was used in a variety of medical diseases. In the actinomycetic infections there would appear to be a wide variability in susceptibility to the drug. Appraisal of its efficacy in brucellosis is withheld.

E. A. GORVETT, M.D.

Barber, M., Nellen, M., and Zoob, M.: Erysipeloid of Rosenbach: Response to Penicillin. *Lancet*, Lond., 1946, 1: 125.

Human infection with erysiplothrrix rhusiopathiae, the organism of swine erysipelas, is sufficiently uncommon for any proved case to be worth recording. Recently, 7 patients with clinically diagnosed erysiploid of Rosenbach were admitted to the hospital, and in 5 of them the diagnosis has been bacteriologically confirmed. These cases are believed to be the first in humans to be treated with penicillin, although Heilman and Herrell (1944) have successfully treated experimental erysiplothrrix infection in mice with penicillin.

Of the 5 cases of bacteriologically confirmed erysiploid of Rosenbach reported, 3 were treated with penicillin intramuscularly, which appeared to effect a complete recovery in 48 hours. These 3 cases and 2 other clinically similar ones were all admitted within a period of 4 months.

BENJAMIN GOLDMAN, M.D.

North, E. A., and Christie, R.: Acquired Resistance of Staphylococci to the Action of Penicillin. *Med. J. Australia*, 1946, 1: 176.

After testing more than 100 strains of staphylococci, Spink, Hall, and Ferris, in 1945, failed to find a single strain not previously exposed to penicillin that was not inhibited by 1 unit of penicillin per cubic centimeter. The authors, also, believe that naturally occurring penicillin-resistant staphylococci are rare. However, a large number of strains isolated from patients receiving penicillin show considerable resistance to this drug by the standard sensitivity tests. Up to this time there was no evidence to indicate whether the resistant strains were descendants of sensitive organisms already in the wound, or contaminants with naturally resistant strains or strains which had acquired resistance and become disseminated through the wards.

JOHN E. KIRKPATRICK, M.D.

Weinstein, L.: Typhoid Bacillus Infection of a Surgical Wound; Treatment with a Urethane-Sulfanilamide Mixture. *N. England. J. M.*, 1946, 234: 184.

In spite of the fact that a moderate number of patients with typhoid fever develop complications requiring operative intervention, such as incision and drainage for osteomyelitis or laparotomy for intestinal hemorrhage or perforation, and that the eberthella typhosa is capable of producing localized areas of infection, there is a scarcity of reports concerning suppurative complications of surgical wounds.

The author reports a case of typhoid bacillus infection in a surgical wound of the leg, without underlying osteomyelitis or periostitis, in a patient who probably had an undetected mild attack of typhoid fever several weeks prior to operation for the open reduction of a fracture of the femur. Had the patient not incurred a fracture of the hip, with subsequent infection of the operative wound by the typhoid bacillus, the diagnosis of typhoid fever would in all probability never have been made.

The manner in which the enteric pathogenic bacteria gained entrance to the wound is open to conjecture. It seems probable that the organisms were not brought to the site of operation by the blood stream, since, if it is assumed that the original illness 3 weeks previously was typhoid fever, the bacteriemic stage should have been over for an appreciable time.

It has been demonstrated that the eberthella typhosa is extremely susceptible to the action of urethane.

Treatment of the local infection with a solution containing 10 per cent urethane and 1 per cent sulfanilamide led to rapid eradication of the infecting bacteria and healing of the wound.

The importance of localized areas of suppuration due to the eberthella typhosa cannot be overemphasized because, unless promptly recognized bacteriologically and the necessary precautions taken, spread of typhoid fever may occur.

HARRY W. FINE, M.D.

Boyd, J. S. K.: Tetanus in the African and European Theaters of War from 1939 to 1945. *Lancet*, Lond., 1946, 1: 113.

The object of this report is to assess the incidence of tetanus in the European and African campaigns of 1939-45; to ascertain as far as possible the extent to which this has been influenced by active and passive immunization; to examine the effect of immunization on the severity of the disease; to discuss the failure of active immunization in preventing the development of tetanus in certain cases; and to consider the results of various forms of treatment and other matters of lesser importance.

The report is based on the records of 103 cases of tetanus in British, Indian, Dominion, and Colonial land forces, in a few Allied troops, and in prisoners of war during military operations in the European and African theaters of war. Most of the patients were battle casualties. Passive immunization against tetanus by inoculation with tetanus antitoxin was used for the first time on a large scale in the war of 1914-18, and its value as a prophylactic measure was fully tested and proved.

It was found that 2 doses of 1 cubic centimeter of a potent toxoid, given at an interval of 6 weeks, produced in most cases a level of circulating antitoxin believed to be adequate to afford temporary protection, and at the same time called into permanent existence a defensive mechanism capable, when stimulated by the presence of further quantities of toxoid (and presumably toxin), of turning out large quantities of antitoxin. Subsequent doses of toxoid produced both a higher level of circulating antitoxin and a more sensitive and more readily stimulated defensive mechanism.

Active immunization against tetanus by means of 2 doses of 1 cubic centimeter of tetanus toxoid given at an interval of 6 weeks was officially introduced into the British Army in 1938, and it is estimated that at the time of the German invasion of Belgium

and France, when the first heavy casualties were incurred, about 90 per cent of the troops on the Continent were protected. Although the advantage of a third dose was fully realized, this was not made a standard procedure until January, 1941, mainly owing to difficulties in procuring the necessary supplies of toxoid. In the Middle East (the theater in which most casualties were being incurred at that time) this order took long to implement, because of the inevitable delay, through transport shortage, in getting supplies from home. Finally, in November, 1942, instructions were issued for an annual "boosting" dose of 1 cubic centimeter of toxoid to be given to all Service personnel. Before the invasion of Europe, the troops in 21 Army groups were practically 100 per cent inoculated. As an additional precautionary measure, a special order was issued, which required that every man who had not already received one or more boosting doses—i.e., every man who had received only the initial 2 doses—should be given a third dose before going overseas. A few managed to elude the net, but their number was small.

Passive immunization was maintained as an additional precaution. Any wounded man who was not actively immunized was given 3 doses of 3,000 international units of antitoxin at weekly intervals. Actively immunized men were given a single dose of 3,000 units as soon as possible after wounding. The object of this dose was to tide the man over the first critical week, during which his circulating antitoxin might be below the safety level. This procedure of combined active and passive immunization was adopted in the United Kingdom, and in the Australian, New Zealand, and Indian armies. In South African troops (U.D.F.) passive immunization alone was used until 1942. In the Canadian and American Army forces, the troops were actively immunized in the same way as in the British Army; however, when wounded they were given, not antitoxin, but a further boosting dose of 1 cubic centimeter of tetanus toxoid, with the object of stimulating rapid antitoxin production.

An analysis of this study indicates that the incidence of tetanus in the African and European campaigns has been negligible. This is attributable chiefly to active immunization with tetanus toxoid.

Active immunization did not prevent the development of tetanus in 22 cases. The case mortality rate among actively immunized men did not fall below the average, but it is noteworthy that the majority of fatal cases were in colored troops.

The case mortality rate in actively immunized men who were given prophylactic antitoxin was significantly lowered.

The duration of the symptoms in actively immunized men who survived was also significantly lowered.

The incubation period in actively immunized men rarely exceeded 20 days, whereas in most of those who were not actively immunized, the incubation period was more than 20 days.

Failure of active immunization appears to be attributable to an inadequate level of circulating

antitoxin in the early stages of infection and is more likely to be remedied by prophylactic antitoxin than by a "booster" dose of toxoid.

Therapeutic antitoxin, to be effective, must be given early in large doses by the intravenous route.

Sedatives, including avertin and pentothal, did not influence the course of the disease, although they were effective in relieving symptoms.

BENJAMIN GOLDMAN, M.D.

ANESTHESIA

Waters, R. M.: *Anesthesiology. J. Am. M. Ass.*, 1946, 130: 909.

Certain abuses associated with anesthesiology are common and accepted practices in our country. Exploitation of the patient by the hospital or anesthesiologist does exist. And often the qualified medical specialist in anesthesia has not the recognition, as a professional member of the medical staff, that he is entitled to. There is often domination of this department by hospital executives or others whose vision of the ideal is blurred by the desire to avoid entries on the debit side of the ledger. It is important to avoid exploitation, and to be sure that sufficient funds are set aside or collected to pay adequately for good service in anesthesiology.

Several organizations of anesthesia service are suggested; the scope of departmental organization and the size of the institution will determine the number of individuals needed. Of importance are the teaching and research possibilities of the specialty. These should be given proper emphasis. Much wasted effort in unnecessary experimentation can be avoided by interdepartmental friendship and understanding throughout the medical school and hospital.

The public as a whole is not receiving the best service that anesthesiology is capable of supplying. This is probably due to the insufficient number of anesthesiologists available. This deficiency is due to a variety of abuses which have become common practice in the hospitals of this country. Proper instruction of undergraduate and graduate students in our medical schools and hospitals is one method leading to improvement and the other is organization of departments in medical schools and hospitals.

This article is a plea to correct the abuses of this specialty at this auspicious time when hundreds of medical officers interested in anesthesiology are returning from war.

MARY KARP, M.D.

Monhelm, L. M.: *Anesthetic Procedures Used in a General Hospital in the Communication Zone with an Analysis of 2,000 Anesthesias. Current Res. Anesth.*, 1946, 25: 67

This is a review of the first 2,000 anesthesias administered in a General Hospital in the Southwest Pacific Theater. Its purpose is to study the technique used and the results obtained, as well as to define the duties of the anesthesiologist.

The anesthetic section has as its duties the establishing of surgical anesthesia, the performance of

diagnostic and therapeutic "blocks," and the administration of intravenous fluids in the operating rooms and oxygen therapy throughout the hospital.

Of the 2,000 anesthesias given, 805 (40%) were by regional methods, 856 (42%) were general; 270 (14%) were local infiltrations, and 69 (4%) were given by combined methods. Four hundred and forty seven of the regional cases were spinal anesthesias and gave gratifying results. The effectiveness of spinal analgesia depends upon the knowledge of the various techniques and the proper selection of cases.

Cervical plexus block and brachial plexus block are described in detail, with a discussion of the new technique for brachial plexus injection. This technique is a combination of the technique used by Lundy and McCluskey, plus a few personal innovations. It has been successful in more than 90 per cent of the 74 cases in which it has been used. It involves the use of 3 needles, the first one contacting the first rib at a point half a finger breadth above the clavicle and just lateral to the subclavian artery. The second and third needles are placed 1 and 2 finger breadths, respectively, posterior and slightly lateral to the first needle, neither exceeding the first needle in depth. A total of 50 c.c. of 2 per cent metycaine solution is used for the block. Procaine or metycaine was the drug used for spinal anesthesia. Of the 856 patients who received general anesthesia, 833 were given pentothal intravenously. It was believed that inhalation anesthesia was less suitable for use in the tropics than regional methods. Nineteen different types of combined anesthesias were used for 69 cases. The most frequent combinations were regional anesthesia plus enough pentothal to keep the patient asleep or drowsy.

Complications were kept at a minimum. The immediate complications included laryngeal spasm, which occurred during pentothal anesthesia, and an occasional depression of the respiration. There was only one complication of pneumothorax following regional anesthesia. Postanesthetic headaches occurred in 3 per cent of the spinal cases.

MARY KARP, M.D.

Fraser, R. J.: *Continuous Lumbar Anesthesia with the Dilution Technique. Current Res. Anesth.*, 1946, 25: 58.

This article describes a technique for spinal anesthesia with dilute solutions gained from more than 6 years of experience in 3,000 personal administrations with no anesthetic mortality. Two thousand of these anesthesias were given with the continuous technique. The dilute solutions were used because it was believed that they produced less metabolic change, fewer discomforts, and less morbidity in the patient.

The agents, employed singly or in combination, were procaine, pontocaine, percaïne, or dilute nupercaine, and the method with which these agents were used was described in detail. A 1 per cent solution of procaine in saline solution especially prepared for lumbar anesthesia was the drug of choice. With this solution the volume is larger and the interval be-

tween injections is closer than with the concentrated solution of procaine. The second injection was usually required 30 minutes after the initial injection when procaine was used and again 15 to 20 minutes thereafter. As much as 35 c.c. of a 1 per cent solution of procaine has been given in chest surgery at one dose with no respiratory paralysis. The continuous technique offers more safety than the single dose technique, and the dilute technique offers a safer procedure than the concentrated technique since the former has less effect on the respiratory, cardiac, and vasomotor systems. No barbotage was used.

Stress was made on the necessity of maintaining a continuity of the continuous lumbar apparatus. Pressor drugs were not used routinely, but were indicated in aged and hypersensitive patients, and included ephedrine, epinephrine, ephedrine-pitressin combination, neosynephrin, and methedrine.

The technique of combining nupercaine procaine or pontocaine glucose was discussed. When pontocaine and glucose were the agents used, a 0.2/10 solution or 0.1/10 per cent solution was found to have the same anesthetic potency as the 1 per cent procaine solution. So far, no intercostal paralysis has resulted from the more dilute 0.1 per cent solution. The use of dilute nupercaine is still in the experimental stage.

The largest volume of procaine in the series was 60 c.c., and the longest anesthesia reported was 3 hours.

MARY KARP, M.D.

Evans, F. T.: Sepsis and Asepsis in Spinal Anesthesia. *Proc. R. Soc. M., Lond.*, 1946, 39, 181

It is the author's opinion that when sepsis occurs in spinal anesthesia, the infective material is conveyed through the lumen of the spinal needle because of some avoidable failure in the anesthetist's technique. The author also stresses the question of asepsis.

There are many points at which the technique can break down. Septic matter can enter the spinal canal as the result of spinal puncture as follows:

1. From the hands of the anesthetist
2. From the skin of the lumbar area
3. From the imperfect sterilization of syringes and needles
4. From contamination of the needles and syringes
5. From a hematoma caused by repeated attempts at spinal puncture

The wisest course is to scrub the hands with soap and water as for any surgical procedure, rinse them in alcohol for 2 minutes, and allow them to dry. Furthermore, the use of sterile rubber gloves, put on in the proper manner, is recommended.

With regard to skin preparation, the preferred method is washing with soap and water, this being followed by the application of tincture of iodine and alcohol. Since it is possible for organisms to be carried in by the needle, either on the point or just inside the lumen of the point, the Sise introducer may be used as a precaution.

The syringes and needles are used for nothing but spinal punctures. All-glass syringes are recom-

mended as infected clots or organisms can lodge in the interstices of the cement in other types and it is difficult for the sterilizing fluid to penetrate these areas. The best method of sterilization is with dry heat or autoclaving. If this is not possible, boiling for 5 minutes in water is reasonably safe, distilled water being used to avoid the risk of an alkaline reaction which will precipitate the anesthetic as its insoluble base.

Distilled water employed for rinsing needles and syringes must be taken from a new bottle that has been freshly sterilized, as organisms can be found in the water after the bottle has been opened for a few hours.

Anesthetic solutions in ampoules are safest, but there is a source of infection via the ampoule. This is the paper label, which will float off in aqueous solutions, and the organisms imprisoned under the label are released and thus form a source of infection. Ampoules may be kept in 70 per cent alcohol or their outer surface may be sterilized by immersion in formalin vapor for 24 hours.

There is some evidence of the occurrence of "chemical meningitis," but this is thought to be negligible.

Direct handling of the ampoules is avoided and the needle is introduced into the ampoule without its touching the exterior.

With proper technique, the risk of infection is negligible, but if there is any deviation from this, infection can occur, and sometimes with disastrous consequences.

MARY FAUCETT FOR, M.D.

Griffith, H. R.: The Physiological and Clinical Action of Curare. *Current Res. Anesth.*, 1946, 25, 45.

This article reviews the history of the present knowledge of the clinical use of curare, with special reference to its use in anesthesiology. The curare effect is observed usually within a minute after the injection is made, reaches its peak in about 5 minutes, and then in 20 minutes it gradually disappears. The proper dose depends upon the anesthetic agent which is used, the size and age of the patient, and the individual susceptibility to the drug. When either is the anesthetic agent used, curare causes more respiratory depression than when it is used as an adjunct to cyclopropane alone. Pentothal does not have the same curariform action as ether, but care must be employed to maintain an adequate respiratory exchange when curare is added to pentothal anesthesia. There is less margin of safety between the effective dose and the overdose in young children than in adults. Frail or seriously ill adults seem to stand the drug as well as robust ones, and need as large a dose in proportion to weight.

The usual initial dose in adults is between 3 and 3½ c.c. Five cubic centimeters is the maximum dose for one injection. Large doses probably bring on the central action of curare rather than the desired peripheral action. Disappointing results follow an attempt to give initial doses smaller than 3 c.c. to

adult patients under cyclopropane or other gas anesthetic agents.

The author has personally administered curare to 700 patients. It is used as an adjunct to cyclopropane in 40 per cent of all abdominal operations. It is useful in facilitating endotracheal intubation in cases in which there is much muscular rigidity, in overcoming the tight anal sphincter in hemorrhoidectomies, in aiding pelvic examinations in obese patients, and in relaxing a conscious muscular patient who is to have a bronchoscopy.

Curare has two actions. The well known peripheral action and the central action on the brain. The peripheral action is due to an interruption of the nerve impulse at the neuromuscular junction, probably a blocking or neutralizing of the acetylcholine reaction. Curare thus prevents the effector substance of voluntary muscle from reacting to acetylcholine, and also blocks synaptic transmission between preganglionic and postganglionic fibers of the sympathetic division of the autonomic nervous system.

Evidence of the central action of curare is based upon recent clinical results following the administration of large doses to patients and the findings in recent laboratory experiments. When large doses were given, complete paralysis of all skeletal muscles resulted with an abrupt loss of consciousness without any preceding period of analgesia. Evidence points to the independent nature of the central and peripheral actions. Prostigmine was not believed to be a necessary antidote to overdose of the drug.

An occasional bronchial spasm resulted from the use of curare. Among the author's 700 cases, 3 bronchial spasms were observed.

There is no contraindication to its use. It may be administered to any patients in whom extra muscular relaxation is needed. Sternal injection may be used when the veins are inaccessible.

The sure but transitory action, with rapidity of elimination and no after effects, makes the use of curare a great benefit to the anesthetist and appears to give this drug a permanent place in anesthesiology.

SURGICAL INSTRUMENTS AND APPARATUS

Jenkins, H. P., and Clarke, J. S.: Gelatin Sponge, A New Hemostatic Substance; Studies on Absorbability. *Arch. Surg.*, 1945, 51: 253.

Hemostasis is a fundamental principle in surgical technique. It can be satisfactorily obtained in most instances by ligature, clips, pressure, electrocoagulation, and packs. There are some situations, however, in which venous or capillary bleeding may be difficult to control by these methods.

The major recent advances in the problem of control of capillary and venous oozing have been the development of coagulating agents, such as thrombin, and the use of absorbable substances which will aid in clot formation by purely mechanical means, such as transmitting pressure to the bleeding surface and offering a matrix for the formation of the clot.

The work of Seegers and his coworkers deserves special mention as a major contribution to the problem of hemostasis. They have developed a method of preparing a purified thrombin, which is now commercially available and, furthermore, they have worked out a method of calibration and standardization of the potency of the thrombin known as the Iowa unit.

The most recent of the absorbable hemostatic materials is gelatin sponge or foam. This is prepared from ordinary commercial gelatin, which is made up in a solution to which a hardening agent is added. After bubbles of air are introduced, the mixture is allowed to dry in pans. It can then be cut into any desired size or shape. The material, which has been used for experimental purposes, is provided in sealed glass jars previously subjected to sterilization with dry heat.

The gelatin sponge is a white crisp material which is extremely light in weight. One cubic centimeter weighs 9 mgm. The sponge will take up many times its weight of water when it is submerged and the air bubbles are expressed.

When moistened, the gelatin sponge shrinks and becomes soft and pliable. It easily adjusts itself to any irregularities in the surface to which it is applied. It does not fragment easily, although it is not especially tough.

An experiment was devised primarily to determine the behavior of the gelatin sponge in the tissues of animals and the response of the tissues to the gelatin. To avoid the introduction of an additional factor in this evaluation, the gelatin sponge was used without thrombin.

These experiments have demonstrated that gelatin sponge is a bland substance which is generally slowly absorbed in the tissues over a period of about 5 weeks.

The presence of a conspicuous number of polymorphonuclear leucocytes would generally lead to rapid absorption of the sponge within a few days or a week by a liquefaction process.

The magnitude of the tissue reaction to the gelatin sponge during the period of absorption was generally less than that observed for surgical gut.

Gelatin sponge has a definite hemostatic action per se when applied to bleeding surfaces with moderate pressure.

Gelatin sponge or foam appears to have properties which make it suitable as an absorbable hemostatic substance, and deserves clinical trial in the varied fields of surgery to further evaluate its merits and limitations.

JOHN E. KIRKPATRICK, M.D.

Lowry, M. L.: Synthetic Adhesives in the Treatment of Wounds of the Liver and Other Surgical Conditions; A Preliminary Report. *Arch. Surg.*, 1946, 52: 160.

With a view to finding a hemostatic agent capable of controlling hemorrhage from extensive wounds, the author has performed experiments on rabbits, and has used commercial Scotch tape to cover de-

fects left by the excision of segments of the liver. Seventeen animals were operated upon and large wedge-shaped portions of their livers were cut away. No attempt was made to bring the two cut surfaces together or to control the bleeding in any way, nor was the tape applied to the raw surfaces of the liver. Instead it was placed on the upper and lower surfaces of the liver and brought out over the defects to the edge of the liver in such a manner as to enclose completely the area from which the excision had been made. One rabbit died of peritonitis on the fourth day. In contrast to this, 8 of the 11 control animals died of hemorrhage within 12 hours; the 3 control rabbits which survived had the smallest liver wounds.

Commercial Scotch tape consists of three layers: the backing, usually cellophane; the filler, rope stock paper; and the adhesive face, crude rubber or some synthetic substitute. Eleven types of tape were tested—the regularly available types and some specially synthesized tape for experimental purposes by the manufacturer. In addition to being used in the animal experiments mentioned, the tapes were tested for absorbability by introducing samples of them into the peritoneal cavities of rats and leaving them there for a month. They were also subjected to sterilization by means of autoclaving.

When the sixteen surviving rabbits were examined, from 1 to 5 weeks after operation, none showed signs of intraperitoneal bleeding or visible residues of the tape. A few showed slight adhesions of the

intestine to the liver scar. The liver wounds had healed well. When the hepatic scars were sectioned for microscopic study a small abscess or a caseous residue surrounded by fibrous tissue was the usual finding, apparently representing the unabsorbed components of the tape. The synthetic resins type of adhesive agent had the greatest hemostatic effect. The most satisfactory type of tape, although it was not completely absorbed, was one of polyvinyl alcohol backing, rope stock filler, and adhesive synthetic resins. The tape samples left in the peritoneal cavities of rats were completely absorbed at the end of one month and produced no tissue reaction. All of the tapes were found capable of withstanding sterilization by autoclaving, but some lost varying degrees of elasticity, flexibility, and adhesiveness in the process.

This type of tape has many potential surgical uses, as a hemostatic agent in wounds with diffuse bleeding, and as a simple mechanical method for holding together the ends of severed nerves, tendons, and possibly vessels. Of the requirements for a product that will be suitable for use in humans, namely, complete absorbability, minimal tissue reaction, great adhesive capacity, good hemostatic effect, and susceptibility to chemical and thermal sterilization, some of these have already been attained. The author believes that with continued investigation, the other desired properties can be obtained.

B. F. LOVINSKY, M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Camiel, M. R.: Roentgenology of the Draining Bronchi from Tuberculous Cavities. *Radiology*, 1946, 46: 24.

The diagnosis of involvement of the bronchi draining tuberculous cavities is, as a rule, based on clinical evidence, bronchoscopic findings, and a few indirect roentgen signs. The author, in studying a rather large number of cases, came to the conclusion that there are also characteristic direct roentgen signs which may be utilized to advantage.

The part of the lung which lies between the hilum and a certain tuberculous cavity contains the regional bronchi and the peribronchial vascular and lymphatic channels which drain the area of parenchymal involvement toward the root of the lung. That the draining bronchi themselves may be involved by the tuberculous process is now generally recognized. Some investigators, as a matter of fact, are of the opinion that they are almost always involved.

The mode of involvement of the bronchi is not clear. There are several theories for its explanation. The author believes that it is the result of direct extension from the cavities they drain by implantation from the infected material.

The roentgen appearance of involvement of the draining bronchi depends on the severity and duration of the underlying tuberculous process. In the early stages the edema or slight inflammation of the bronchus is reflected in a simple increase of the bronchial shadow. The often observed rapid clearing up of such a shadow suggests either a nonspecific process or a very minimal tuberculosis. Later, submucous extension develops with elevation of the bronchial mucosa and thickening of the bronchial wall. At this stage roentgen study reveals two closely related, dense, parallel lines, separated by a central shadow caused by the lumen. Tomography is of great help in bringing out this feature of the roentgen appearance. Still later, ulceration develops and is associated with an irregular granulomatous growth above the surface. Such a process is identified on the roentgenogram by a dense irregular widened bronchial shadow with an irregular narrowing of its lumen. A peribronchial reaction may also be present.

At times one may not be able to outline the bronchus clearly, but even so the shadows between the cavity and the hilum are attributed to the involvement of the draining bronchi. With continued advance of the tuberculosis the ulcerogranuloma completely occludes the bronchus, which leads to peripheral atelectasis. Finally, caseation sets in with necrotic bronchitis, and gives rise to very thick bronchial and peribronchial shadows. The clearing of the extensive disease is reflected by a reversal of the roentgen findings until a gradual return to

normal is reached, although the fibrous residua may leave their marks indefinitely. T. LEVCUTA, M.D.

De Balsac, R. H., and Pannier, R.: Cardiovascular Radiokymography; Its Usefulness and Its Future (La radiokymographie cardiovasculaire; son utilité et son avenir) *Rev. belge sc. med.*, 1945, 16: 1.

Radiokymography offers two ways of picturing the movements of the heart and the great vessels. In the first a screen with horizontal slits is interposed between the thorax and the photographic plate. The screen is slowly moved down vertically till the whole plate has been exposed. A picture of all parts of the heart in various phases is thus obtained. In the second method, the screen is stationary and the plate is moved till fully exposed. The resulting picture shows the movements of particular areas of the heart in its various phases. The kymogram enables us to distinguish clearly between moving and nonmoving contours.

The clinical importance of this diagnostic method is still open to question as the interpretation of the kymogram presents considerable difficulties. However, valuable contributions seem to be possible in cases of coarctation and stenosis of the aorta, in localization of foreign bodies in the wall of the heart, and in valvular diseases. This article deals especially with the radiokymographic findings of myocardial infarcts, and the systolic dilatation of the left auricle in mitral disease. WERNER M. SOLMUTZ, M.D.

Hendelberg, T.: The Roentgenographic Examination of the Ankle Joint in Malleolar Fractures. *Acta radiol.*, Stockholm, 1946, 27: 23.

A number of different studies of the mechanism of various ankle fractures and dislocations and of their anatomical basis are loosely linked together in this article, the material being mainly from the author's thesis on fractures of the posterior margin of the tibia.

Some of these investigations may be summarized as follows:

1. *Purpose of the investigation.* The determination of the origin and insertion of the anterior tibiofibular ligament, and of its relation to the common oblique fracture of the tibia.

Method. Radiography of an anatomical preparation in which the ligament was marked by a wire.

Findings. This type of fracture often reaches below the insertion of this ligament. If the malleolus can be displaced laterally by manipulation, the ligament is invariably torn even if the fracture does not reach below the ligament.

2. *Purpose of the investigation.* Study of the lateral and medial malleolar ligament insertions for better understanding of the arthograms.

Method. Radiography of an anatomical preparation from which the posterior joint capsule was removed.

Findings. The medial ligament inserts on the astragalus at the level of the distal part of the trochlea tali. The lateral ligament inserts at the level of the subtaloid joint.

3. **Purpose of the investigation.** Study of the injuries to ligaments caused by malleolar fractures.

Method. Manipulation of fractured ankles under fluoroscopic control.

Findings. In 31 of 42 cases examined a tendency toward dislocation was observed. The dislocation could be produced by pronation-abduction in 24 cases, by supination-adduction in 2, by supination in 2, and by uncertain or unidentified motion in 3 cases.

4. **Purpose of the investigation.** Comparison of the mobility and "dislocatability" of the injured ankle with that of the uninjured one of the same patient.

Method. Manipulation under fluoroscopic control.

Material. Approximately 250 cases with fresh or old (follow up) ankle injuries.

Findings. Only one control ankle displayed a slight instability of the talus. No instability of the talus in plantar flexion was observed in any control ankle, although it had been described as a normal feature by many anatomists.

Conclusion. A mobility of the talus which permits widening of the talofibular space under manipulation is pathological.

5. **Purpose of the investigation.** Correlation of the fluoroscopic findings in 4 to specified ligament injuries.

Method. Arthrography by means of injection of 3 c.c. of perabrodil into the joint.

Material. Same as in 4.

Findings. In 15 of 16 cases in which the attempt at dislocation of the injured ankle failed or in which the fractured malleolus accompanied the talus in dislocation, no leakage of contrast material occurred. In 9 of 10 cases with gross abnormal mobility of the talus, leakage was clearly observed.

Failure of contrast material to escape into the surrounding tissues in some cases of abnormal "dislocatability" was probably caused by blood clots because it occurred in cases in which the examination was performed 24 hours after the injury or later. Nonleakage in cases of abnormal mobility not exceeding 1 or 2 mm. (observed in a few instances) is probably explained by stretching of the capsule without rupture.

6. **Purpose of the investigation.** Determination of the roentgenographic visibility of the widening of the tibiofibular space (which is said to occur in many ankle injuries).

Method. Insertion of wooden wedges between tibia and fibula.

Findings. The widening cannot be seen on regular anteroposterior ankle films because of the obliquity of the contours. Escape of contrast material along the interosseous membrane sometimes indicates this.

Conclusion. Fluoroscopic manipulation and arthrography are necessary for the x-ray diagnosis of rupture of the tibiofibular ligament.

7. **Purpose of the investigation.** Determination of how tilting or dislocating the talus influences the tibiofibular ligament and space.

Method. Postmortem experiments and the testing of 1 case in vivo.

Findings. Dislocation of the talus does not widen the tibiofibular space.

8. **Purpose of the investigation.** Evaluation of the roentgenographic visibility of posterior tibial fragments.

Method. Postmortem experiments with artificial fractures and clinical roentgenographs of 160 cases.

Findings. Only in 27 of the 160 cases were the fragments clearly outlined.

Conclusion. Films of the ankle in oblique posterolateral projection should be taken in all cases of ankle injury.

Further studies concerning fractures of the malleolar arches are discussed in detail.

GERHART S. SCHWAB, M.D.

Overgaard, K.: On Bechterew's Disease from the Roentgenological Point of View. *Acta radiol.*, Stockh., 1945, 26: 185.

The author briefly reviews the pathology of ankylopoietic spondylarthritis, or Bechterew's disease, and stresses its frequently insidious onset, its predilection for young adult males, the pain in the spine with gradual development of poker spine, especially in the lumbar region, fixation of the ribs, and later involvement of the joints of the extremities.

He points out that the few cases reported as coming to autopsy relatively early in the disease process have shown an inflammatory arthritis first affecting the small intervertebral joints, which ultimately results in fibrous and then bony ankylosis, with accompanying deposition of bone in the vertebral ligaments. Whereas the state of the sacroiliac joints is not mentioned in these early autopsies, the author believes there is roentgen evidence pointing to similar early involvement of these joints, which is much more easily recognizable in films than in the small intervertebral joints where such changes can at best be brought out only with a careful search of special oblique views.

He bases his opinion on a study of 31 personally observed cases (28 males and 3 females) and gives the roentgen details in 8 of these cases. Early in the disease there were scattered opacities in bone about the sacroiliac joints with slight, spotty decalcification of subchondral osseous tissue and blurring of the articular surfaces. Confluence of the small rarefactions may result in an apparent increase in cartilage space. As decalcification spreads in some areas, sclerosis increases in others, and bony bridges begin to cross the articular interspace. Gradually this process progresses until the joint architecture is effaced by osseous ankylosis.

He also calls attention to the fact that although the fibrocartilaginous tissue in the center of the discs degenerates as the disease progresses, the vertebral interspaces usually do not become narrowed, as

in simple fibrous degeneration, probably because by the time this change intervenes the distance between the vertebrae has become fixed as a result of articular and ligamentous change, manifested in the roentgenogram by intervertebral bridging and not to be mistaken, in the author's opinion, for the long osteophytes often seen in ordinary osteoarthritis.

After reviewing the results of roentgen therapy in this disease as reported in the literature, the author relates his own experience in the treatment of 15 patients with rather severe cases, who also received intensive medicinal and physical therapy. Irradiation was given over the sites of pain, with special attention to joints in which it was important to maintain mobility, such as the cervical and atlanto-occipital joints, and those of the hip and shoulder. Single doses of from 150 to 200 r. (180 kv., 1 mm. of copper plus 1 mm. of aluminum), repeated once to a given field, or one dose each to an anterior and posterior portal, constituted the usual course, and if a satisfactory effect was not obtained the course was repeated after from 3 to 6 weeks. A considerable analgesic effect was obtained in all cases, and as a consequence patients were able to tolerate more active physiotherapy. A follow-up of 10 cases after from 1 to 4 years showed that the gains made had been maintained in all but 1 incompletely treated case. The patients had little pain, and mobility in the joints of the extremities was good enough to permit them to work. LILLIAN DONALDSON, M.D.

Nielsen, J.: Roentgen Treatment of Malignant Tumors of the Nasopharynx. *Acta radiol.*, Stockholm, 1945, 26: 133.

The author reports his experience with 77 cases of malignant nasopharyngeal tumors, 75 of which had been examined histologically. This represents the total number of cases of this kind referred to the Radium Center in Copenhagen from 1931 to 1941, and 0.75 per cent of all malignant affections treated in this institute over this period. Several histological classifications in the examined tumors are given, one of which is as follows:

Lymphoepithelioma	22 cases
Reticulosarcoma	13 cases
Lymphosarcoma	7 cases
Basal cell carcinoma	12 cases
Squamous cell carcinoma	20 cases
Cylindroma (cylindrocellular carcinoma)	1 case
Not examined	2 cases

All cases were treated with x-rays exclusively in fractionated doses to two lateral portals (including the base of the skull and the neck) and usually to two additional frontal portals with the eyes protected. As a rule, two treatments were given per day. The single treatment dose varied between 75 and 200 r./air. In most cases the radiation was a heavily filtered (Thoraes filter) 180—200 kv. beam. The target skin distance was between 50 and 70 cm. and the intensity varied between 2.5 and 7.5 r./air per minute. The tumor doses as stated in the case histories (not all of the cases are reported) ranged

from 1,800 r. to 5,400 r. Additional treatments were given to recurrences and metastases.

The results in the 37 cases which were treated up to 1936 were as follows:

TABLE I.—ROENTGENOLOGICAL RESULTS IN 37 CASES OF NASOPHARYNGEAL TUMOR OBSERVED FROM 1931 to 1936.

Symptom-free after 5 years	9 (24 per cent)
Alive with recurrence after 5 years	2 (5 per cent)
Died within 5 years	26 (71 per cent)

37

TABLE II.—FIVE-YEAR RESULTS OF ROENTGENOLOGICAL TREATMENT IN 37 CASES, IN RELATION TO THE HISTOLOGIC TYPE OF THE NASOPHARYNGEAL TUMOR.

Lymphoepithelioma	4 of 15	} Sarcomas: 7 of 25 (28 per cent)
Reticulosarcoma	2 of 7	
Lymphosarcoma	1 of 3	
Basal cell carcinoma	2 of 2	} Carcinomas: 2 of 9 11 (18 per cent)
Squamoepithelial carcinoma	0 of 9	
No microscopy	0 of 1	

Sixty-seven of the 77 patients either had lymph node metastases when they were first seen or they developed them after the treatment. In 25 cases distant metastases could be demonstrated with certainty in one or more of the following locations: bones (12 cases), mediastinum and lungs (8 cases), liver (3 cases), and abdominal glands (7 cases). The author concludes: (1) that roentgen therapy is at present the method of choice; (2) that supplementary intracavitary treatment will probably not improve the results since the dose distribution is adequate; and (3) that in cases of lymphoepithelioma the necessary tumor dose depends on the treatment time. It rises with the treatment time, e.g., it is only 3,000 r. if given in 20 days, but 5,100 r. when protracted over 60 days.

The symptomatology, diagnosis, and clinical management of nasopharyngeal tumors is discussed extensively. GERHART S. SCHWARTZ, M.D.

Jensen, A.: Dose Measurements in Roentgen Irradiation of the Female Pelvis. *Acta radiol.*, Stockholm, 1945, 26: 99.

The purpose of this investigation is to compare the skin dose-tumor dose ratio as it occurs in the roentgen ray treatment of the parametria following the usual intracavitary radium treatment of uterine carcinoma, (a) if cross firing through 2, 4, or 8 portals is used, and (b) if rotation treatment is applied. In the latter case the patient lies horizontally on a stretcher while the roentgen ray tube moves around the patient.

Three principal arrangements were used for the rotation method: (1) the tube describes a half circle of 180 degrees around the long axis of the patient within several minutes; then the patient is turned

from her back onto her abdomen and the circle is repeated so that a continuous skin belt around the pelvis is exposed to roentgen rays; (2) two complete circles around the patient are described by the tube, the radiation being angulated first toward the feet of the patient, and later toward the head of the patient, which results in 2 x-ray exposed skin belts which cross each other; (3) rotation around 2 parallel long axes 12 centimeters apart. In this arrangement, only a limited sector is described by the tube around each side of the patient.

The measurements were taken on an anatomical preparation, on a paraffine-dichlorobenzol phantom, and on actual patients. Sievert ionization chambers were used on the surface and within the test objects. An intravaginal thimble chamber of a Siemens dosimeter was used on patients.

The speed of the circling tube was varied. In some experiments it was constant, and in others the tube was purposely slowed up over certain sectors. The author found that the best dosage distribution and the optimal skin dose-depth dose ratio could be obtained in the third arrangement, and that it was superior to all arrangements of group 2. This is explained by the fact that the uterus received an adequate dosage from the radium treatment alone, so that the roentgen radiation should be concentrated to either side of the uterus in the parametria. The measurements for all tested arrangements are given.

GERTHART S. SCHWARTZ, M.D.

Robbins, L. L., Aub, J. C., Cope, O., and Others: Superficial "Burns" of the Skin and Eyes from Scattered Cathode Rays. *Radiology*, 1946, 46: 1.

The authors' report is concerned with varying degrees of injury received by 6 men at the Massachusetts General Hospital, Boston, as a result of exposure, for a few seconds, to scattered electrons from a 1,200 kv. electrostatic generator.

The effect of exposure to cathode rays in the direct beam was known, but the effect of scattered cathode rays was not understood. Previous workers have observed clinically and experimentally that the effects of cathode and roentgen rays are similar, except that the former have a definite and limited depth of penetration involved in underlying reaction. The energy that of roentgen rays. This is readily understood when it is realized that in the production of the latter, probably only 0.5 per cent of the energy of the electron stream is converted into roentgen rays.

On December 1, 1944, in the supervoltage treatment room, the target had been removed from the tube of the 1,200 kv. electrostatic generator, and the cathode ray window inserted. This was necessary to correct the focal point as to size and location. The danger from the direct beam was known, but it was thought that if a reasonable distance were maintained, there could be no great danger for a short period of time. Consequently, 6 men entered the room while the machine was in operation. The machine had been running no longer than 2 minutes,

and each man stood at least from 3 to 5 feet or more away from the central beam and at right angles to it. At one point all of them leaned down, and for 5 seconds or less looked up at the cathode ray window to observe its fluorescence.

Following the accident it was realized that approximate ionization measurements should be obtained in order to estimate the dose and depth of penetration of the irradiation received by those who were in the room. The source of radiation was a vertical 1,200 kv. cathode ray beam emitted through an 0.005 cm. thick aluminum window in the tube, which was 175 cm. above the floor. It was previously known that the maximum range under these conditions is 5.4 mm. in water and probably 450 cm. in air. The beam current was estimated at about 5 microamperes. To obtain the ionization dose measurements in the tissue of those who were irradiated, measurements of the ionization intensity in a phantom were made. The Victoreen R meter gave approximately the same readings. It was estimated that those who stood 100 cm. from the cathode port for 20 seconds received a skin dose of about 1,000 r on their faces and 2,000 r. on their hands. The dosage to the feet would be greater, but this region was well protected by clothing. The measurements also show that the effects will be limited entirely to the first 3 mm. below the surface and will be greatest in the first mm. The effect of cathode rays and of roentgen rays may be similar in regions receiving the same ionization dosage; however, the distribution of energy absorption in the body from cathode rays is very different from that of roentgen rays.

The exposures to cathode rays produced burns which were analogous to but different from sunburn, thermal burns, and roentgen ray burns. The primary reaction was prompt in appearance and was like a very intense sunburn but was not followed by tanning. There were early signs of irritation to the conjunctivae. The first phase lasted from 5 to 7 days.

The secondary phase occurred in from 10 to 15 days after exposure and was characterized by pain of the face and nailbeds, followed by a second increase in redness and edema of the involved parts. The edema was limited to the skin, and in the 3 severe cases bleb formation occurred. In the 3 milder cases the pain and edema disappeared after from 5 to 7 days, and the patients suffered no further symptoms.

The 3 severe cases exhibited a tertiary phase in approximately 4 weeks after exposure. They showed new areas of involvement, appearing at varying intervals, in parts which had been protected by clothing, and these followed the same characteristics as the primary phase—some going on to pigmentation, edema, bleb formation, and even whole thickness skin destruction. Several older areas which had healed broke down for a second time. The most severe case which developed full thickness skin loss from the blebs that started in the secondary phase became more extensive and ruptured. The transudate from the wounds became purulent, and bacteria typical of normal skin flora were obtained.

penicillin proved effective in controlling this complication. Grafting was necessary to heal this skin defect.

In addition to thermal burns, there was an absence of subcutaneous edema, which suggests a superficial effect and therefore absence of damage to the capillaries. None of the lesions involved tissues deeper than the dermis.

In comparison with severe roentgen ray reactions, the cathode ray reactions became manifest much sooner and caused decidedly less pain. Their periodicity is unique. They exhibited temporary lulls during which beginning healing was evident.

The late effects are somewhat similar to roentgen ray reactions, but what the final changes may be is still unknown.

An excellent clinical description is given of the cathode ray burns and protocols, and the article is accompanied by colored photographs showing the progress of the cases. HARVEY S. ALLEN, M.D.

RADIUM

Medical Officers of the First, Third, Eighth, Twelfth, and Fifteenth Air Forces: The Use of Radium in the Acrotitis Control Program of the Army Air Forces. *Ann. Otol. Rhinol.*, 1945, 54: 650.

The medical officers of 5 Air Forces participated in the preparation of a report on the use of radium in the Acrotitis Control Program. The organization of the program began in May, 1944 when the Air Surgeon assigned 10 otologists to the Johns Hopkins Hospital, Baltimore, to be indoctrinated, under the guidance of Samuel J. Crowe, in the problem of acrotitis and its possible control by the radium treatment of lymphoid hyperplasia about the pharyngeal ostia of the eustachian tubes. These otologists were then sent to the various Air Forces, some stationed in the United States, others operating in the theaters of war where they actually carried out the work.

The Program became necessary because of the fact that a great number of airmen had been incapacitated by the acrotitis, which interfered seriously with the efficiency of the Service. In referring to the overseas situation in the years 1943 and 1944, one Air Force Theater Surgeon stated: "In the end, these men take up a lot of time of the Unit surgeons, occupy hospital beds, and are not available for combat duty a third of the time."

The term "aero-otitis media" was coined in 1937 by Armstrong and Heim, who defined the condition as an acute or chronic traumatic inflammation of the middle ear due to improper ventilation during flight. Normally, equalization of pressure between the middle ear and the surrounding air is accomplished by swallowing, yawning, or other acts which cause the eustachian tubes to open at regular intervals. Certain predisposing factors, the most common of which is lymphatic hyperplasia in and around the pharyngeal ostia of the eustachian tubes, however, prevent such an equalization of the pressure. The result is that the eustachian tubes become completely

blocked, and cause pain, tinnitus, and deafness of varying degree and duration. This occurs especially during changes in barometric pressure associated with rapid descent. In severe cases, fluid or blood may accumulate in the tympanum and occasionally the drum may perforate.

Otoscope examination reveals retraction and congestion of the tympanic membrane, and often hemorrhage into its layers. Nasopharyngoscopic examination shows that in the majority of such cases there is evidence of excessive lymphoid hyperplasia in the fossa of Rosenmueller, in and around the pharyngeal orifice of the eustachian tube, or in the area between the tubal orifice and the posterior end of the middle turbinate.

Because of this striking correlation between the lymphoid hyperplasia and the incidence of acrotitis in the airmen, it was decided to try to destroy the lymphoid hyperplasia, not only in the men who had already developed a chronically recurring acrotitis but also, if possible, in all those in whom the location and amount of lymphoid hyperplasia would indicate a predisposition to acrotitis. The Air Surgeon authorized the use of radium as the most efficient means of destroying the lymphatic hyperplasia.

The following technique was recommended:

Two nasopharyngeal radium applicators, each containing 50 mgm. of radium sulfate, are introduced simultaneously along the floor of the nose, one on each side. The applicator consists of a radium-containing chamber and a wire handle. The chamber is made of monel, 2 cm. long, has an outside diameter of 2.3 mm., an inside diameter of 1.7 mm., and a wall thickness of 0.3 mm. The chamber is brazed to the wire handle to prevent the possibility of its being broken off and swallowed or aspirated. In the beginning the exposure was for 6.6 minutes, giving a dose of approximately 1 gm., 20 seconds. Later, the exposure was increased to 8.5 minutes, leading to a dose of 1 gm. 25 seconds. With the 0.3 mm. monel filter, the radium source emits 30 per cent beta rays and 70 per cent gamma rays. Whenever possible, 3 applications are made at intervals of from 25 to 30 days.

Treatment should not be given in the presence of an acute upper respiratory infection. In subacute infection, the dose is split into two equal fractions, given 5 days apart. Special care must be taken not to bend or break the applicator since the escape of radon would render the radium useless as a source of irradiation. It is also necessary to observe strict protective measures for the personnel giving the treatment. The best protection being distance, the treatment rooms should be at least 20 feet away from the examining rooms. The applicators must be handled as briefly as possible. To clean them, a soft brush is fastened to the sink and they are rubbed against this brush.

To secure comparable results, the Air Surgeon devised standard methods of history taking, of examination, of interpretation of findings, and of treatment.

The First Air Force was located in the United States. The program was conducted by Hendricks, Lieberman, Lyman, McMurray, Magnuson, and Weymuller. There were two Irradiation Clinics, one at Westover Field, Massachusetts, and the other at Mitchell Field, New York.

During the period from September 10, 1944 to June 1, 1945, Hendricks and Lieberman, after examining 3,525 airmen in combat crew training at Westover Field, found an incidence of 44.3 per cent of lymphoid hyperplasia in and around the eustachian tubes, which required treatment. A past history of aerotitis was two and a half times as frequent in the men who were treated as in those who were rejected for treatment. In a group of 778 airmen, it was possible to extend follow-up observations to 30 days or more after 3 treatments were given. Of these, 90 per cent showed a definite reduction in the amount of lymphoid tissue, as compared to that found at the original examination. In 54 per cent of the men there was subjective improvement. Upon completion of treatments, the incidence of aerotitis in the treated men became practically identical with that of the group who were rejected for treatment.

Weymuller and Magnuson, during the same period, treated 52 cases of recurrent aerotitis at Mitchell Field. Only 8 cases failed to respond, the most frequent causes of failure being allergy, chronic sinusitis, vasomotor rhinitis and sinusitis, and frequent colds.

The Third Air Force likewise was stationed in the United States. The program was conducted by Gleuber, Smith and Earl. There was one Irradiation Clinic established at Drew Field, Florida. In this Air Force, 1,177 flying persons were treated. In 381 cases, a good follow-up was obtained. The subjective improvement amounted to 54.4 per cent after the first treatment, and 90.5 per cent after the second treatment. Objective improvement was noted in 95.2 per cent after the second treatment. Unfortunately, no observations could be made after the third treatment but it is presumed that the final results must have been even higher. The most frequent causes of failure were grossly hypertrophied adenoids, recurrent colds and nasopharyngitis, and permanent defects either in the tympanic membrane or in the nose.

The Eighth Air Force was located in England, from where it operated over the continent. The Aerotitis Control Program was conducted by 3 medical officers, one attached to each division: Eschenbrenner, Jr. to the First, Collins to the Second, and Lyle to the Third Division.

The period of examinations and treatments was from November 1, 1944 to February 14, 1945, but some follow-up studies were continued until June 1, 1945. A total of 1,124 men with aerotitis were examined. Of these, 977 were bomber personnel and 147 were fighter pilots. Treatment was given in 404 cases and a group of 66 untreated cases were used for control. A subjective improvement was noted in 58.3 per cent of the men after the first treatment, in

77.0 per cent after the second treatment, and in 78.2 per cent after the third treatment. The corresponding objective improvement was 78.4 per cent after the second and 94.6 per cent after the third treatment. It was noted that persons with repeated groundings for aerotitis had a high incidence of air difficulty in the decompression chamber.

The Twelfth Air Force operated through Corsica, northern Italy, France, and Germany as a very highly mobile unit. The Aerotitis Control Program was entrusted to Mikell who, during a few months, had to cover with his Irradiation Clinic 20,000 miles by air and 5,000 miles by land, using every imaginable vehicle for transportation. From December 21, 1944 to April 21, 1945, Mikell examined 704 men of whom 394 received treatment. It was possible to follow up 162 men 30 days after the third treatment. The final results showed 89 per cent of subjective and 80 per cent of objective improvement.

The Aerotitis Irradiation Clinic of the Fifteenth Air Force was in charge of Trappaso, who travelled between bomb groups by jeep and trailer. From November 9, 1944 to April 21, 1945 Trappaso examined 1,580 men and treated 1,002 men. However, because of the rapid turnover of personnel, only 91 men could be followed up 30 days or more after the third treatment. The subjective improvement amounted to 44 per cent after the first, 64 per cent after the second, and 81 per cent after the third treatment, whereas the objective improvement was 76 per cent after the second, and 98 per cent after the third treatment.

A tabulation of all the available data from the five Air Forces indicates that a total of 14,345 men were examined by the participating units and 6,881 were selected for treatment. A total of 14,045 treatments were given without a single instance of burn or ulceration. The only reaction noted by a small proportion of the men was a mild stuffiness of the nose or a slight sore throat.

The final conclusion is drawn that radium, by destroying lymphoid hyperplasia in and around the pharyngeal orifices of the eustachian tubes, is of definite value in aerotitis, not only as a curative agent but also as a prophylactic measure.

Reynolds, L.: Newer Investigations of Radiation Effects and Their Clinical Applications; Far-coast Lecture. *Am. J. Roentg.*, 1946, 55: 131.

The mechanism of the reaction which occurs when a patient is treated with a beam of radiant energy has been an intriguing problem from the earliest days of radiation therapy. A worth while theory was not advanced until 1922 when Dessauer published his "point heat hypothesis." According to this theory the absorption of radiation is discontinuous, the energy ultimately becoming concentrated in a few discrete entities within the cell. Only the energy in the form of heat liberated at these points was thought

Fig. 1. This shows a monomolecular layer of lipid material prepared on the surface of water and exposed to only 600 r. of 550 kv. radiation. In this case the radiation enters through the bottom of the thin aluminum pan and passes through a 2 cm. layer of water before it hits the monolayer. In this way, the beam is brought to equilibrium with its secondary electrons. It can be seen at once that the beam, which entered through a small square portal under the pan, has imprinted itself clearly on the monolayer on top of the water.

to cause any effect. The "point theory" was modified by Crowther in 1938 and assumes that action takes place whenever a pair of ions are liberated within the sensitive target area. This phenomenon was thought to be due to a "hit" of the biological structures by the radiation. Other investigators interpret a "hit" as the absorption of a photon.

In contradistinction to this discontinuous effect a more generalized action was assumed by proponents of a second theory commonly known as the "poison theory." The poisonous material was produced by radiation of the nucleus, which then produced death or injury of the entire cell. Failla, in 1937, in his "fluid flow theory" assumes a general effect through change in the ratio of the "radio ions" and the photochemical products on the two sides of the cell membranes. This creates a change in the fluid flow which leads to alteration of the cell properties.

The author, in his experiments, directs attention to certain physicochemical reactions which may influence the equilibrium between the intracellular and extracellular medium, as well as the function of the intervening cell membrane.

The osmotic pressure of a solution of 1 per cent egg albumin was studied after irradiation with 12,000 r. at 550 kilovolts. The osmotic pressure was increased to 78 per cent and was proportional to the dosage administered. The osmometer developed by the

Fig. 2. This shows the form of some of the amino acid groups of which these large protein molecules are built. The simplest one, of course, is alpha amino acetic acid (glycine). In the chart the hydrophilous groups are to the right of the line drawn vertically through the molecular formulas. A number of very interesting things about these hydrophilous groups are immediately apparent. In the first place, every alpha amino acid has both a negative and a positive group attached to the same carbon atom on the end of a hydrocarbon chain. Some of the more complicated ones also have either a positive or a negative one elsewhere in the chain. This gives rise to the familiar peptide linkage by means of which one of these acids can join with another. When we come to consider their solubility in water and their chemical behavior, it is obvious that they will be attracted differentially by acid or basic solutions.

author is a modification of the one designed by Fazer and Myrick. Details of its construction are given. A second osmometer was built according to the plans of Bourdillon, a special membrane material of protein composition being used. The results with this instrument were the reverse of the previous findings. Upon analysis it was found that the membrane had become permeable to the breakdown products of the albumin, and the osmotic pressure had been lowered. An analogy was drawn from these results to the biological effects observed in a dog's brain after x-radiation. One part of the brain showed rather marked intracellular edema. Another part which had received larger dosage showed marked shrinking of the cells. These shrunken cells were thought to be due, not to rupture of the membrane, but to the passage of small protein fragments through the cell membrane (since the chromatin remained intracellular). In the second group of experiments a monomolecular layer of unsaturated lipid material prepared on a surface of water was irradiated with 600 r.

at 550 kilovolts. The beam was directed through a 2 centimeter layer of water. The shape of the emerging square beam can be seen imprinted on the monolayer on top of the water in Figure 1. Further experiments show that greater doses of x-rays were required to produce the same change in a more completely saturated fatty acid. In some cases the surface required ageing to bring about this effect. It has been shown by numerous investigators in the field of physical chemistry that fatty acid molecules in a monomolecular layer will orient themselves at a water-air interface, so that the carboxyl group or polar group is in the water and the hydrocarbon chain or nonpolar group stands erect in the air. In a similar fashion amino acids or proteins are also composed of polar and nonpolar groups and will orient themselves at an interface. Figure 2 is an example of the amino acids in which the hydrophilous or polar groups lie to the right of the vertical line and the hydrophobic or nonpolar groups lie to the left. These oriented monomolecular layers have definite physical properties—they resist cleavage and compression with varying degrees of strength according to their chemical and physical composition. It has been shown that lipoid substances will combine with protein monolayers. Such a combination probably represents our nearest approach to the cell membranes. These membranes are dynamic complex structures which respond to small physical and chemical changes of environment.

Lecithin, an important constituent of brain and nerve tissue, is a highly polar molecule. Multiple monolayers of lecithin (arranged like a stack of cards) exhibit strong optical properties. These optical properties are destroyed by x-radiation. An analogy is drawn between the loss of optical properties of the multilayers of lecithin and the loss of optical properties of myelin when exposed to x-radiation.
